INDEX

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Authors of papers read at the Liverpool Meeting of the British Association are requested to favour the Editor of "NATURE" *with copies or abstracts of their communications as soon as possible, addressed to him at the Post Office in the Reception Room, as by these means alone can an accurate and early notice be insured.*

The Editor appeals to men of Science to aid him in his attempt to give an account of their investigations to their fellow-workers throughout the world.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

One of the leading objects of this periodical is to awaken in the public mind a more lively interest in Science. With this end in view it provides original Articles and Reviews, written by Scientific men, and illustrated when necessary, expounding the grand results of scientific research, discussing the most recent scientific discoveries, and pointing out the bearing of Science upon civilization and progress, and its claims to more general recognition, as well as to a higher place in the educational system of the country. There will also be found in "NATURE" *complete Abstracts of all important Papers communicated to British, American, and Continental Scientific Societies and periodicals, and Reports of the Meetings of Scientific Bodies at home and abroad. In the columns devoted to Correspondence an opportunity is afforded for the discussion* *of scientific questions of general and popular interest. The Journal has now been nearly a year in existence, and having helped to promote many of the objects which all scientific workers have at heart, has, it is hoped, already made good its claim to the support of all who really desire the advancement of Science. Appended is a List of some of the eminent men who have already contributed to the pages of* "NATURE," *or have otherwise aided to establish it.*

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

THURSDAY, MAY 5, 1870

TO OUR READERS

THE opportunity afforded by the commencement of a new volume is one we cannot allow to pass by without a few remarks on the work on which we are engaged, although it may be that such a course is not strictly in accordance with precedent, but our excuse lies in this—our journal is not according to precedent.

For, in fact, six months ago a scientific journal, in which the leaders of scientific thought, in this and other lands, gave week by week an account of their own and others' labours to their fellows and the general public, was a thing of the future, and, in the general opinion, to attempt to start such a journal was almost certain to end in signal failure. "Science is so small, her victories are so few," said some, "that a weekly account of them is altogether beside the question—the well would run dry." Others said: "Science is large, it is true, but her followers are not numerous. You may perhaps number your readers by hundreds, if you take care to appeal to scientific men only; but as for the outside world, they care nothing for science." On the other hand it was held that a popular scientific weekly journal would, be a certain success under certain conditions—some such as these: in the first place, the articles were to be light as air; each fact was to be clothed in a delicate atmosphere of adjective and imagery; next, each page was to be studded with beautiful pictures, correctness both in text and illustration giving way to a certain more or less subdued sensationalism; and lastly, and above all, every care was to be taken to spare the reader the least trouble in the matter of thinking.

We confess that we should have shrunk from our task in the face of such advice as this, had there not been certain Signs of the Times which did not seem difficult to read, and which were more in harmony with the encouragements we received to undertake it; and now that the first volume has been completed, we have the satisfaction of knowing that none of these gloomy forebodings have been realised.

A consideration of the facts brings us at once to our first duty, which is to tender to the scientific men, both at home and abroad, who have assisted us, our best thanks for all their help in the work we have undertaken. We willingly acknowledge the small part we have borne in what has been done. Thanks are due, not only for criticism and the contributions which have already appeared, but for many others which—Nature is so large, and our journal is so small—we have not as yet been able to place before our readers. It has been our endeavour to carry out our programme by making the journal useful to workers in science; worthy therefore of their perusal, and therefore, again, worthy of their contributions: and by thus extending our appeal beyond the limits of the scientific world on the one hand, and endeavouring to keep up the dignity of science herself on the other, we have already met with an encouraging response. Our subscribers now number nearly five thousand; that is, we have, on a moderate estimate, fifteen thousand readers. Though we think this an emphatic success, we shall not be satisfied if the increasing interest in Science, and an increased knowledge of the periodical, do not in a short time double our present circulation, and we trust not only that each worker will urge his neighbours to send us facts, but that each of our present readers will form a nucleus of new ones.

We state this, not only because the statement is almost due to our contributors as a justification of our demands upon their time, but because it indicates the work—we had almost said the noble work—which lies before them. Surely at a time when England would gain so much by the scientific education, not only of her Workmen but of her Ministers, an attempt to place Science before the Public, week by week, as Politics, Art, Music, and a hundred other things are placed before them, must not be suffered to flag; when the number of science-teachers and science-students is daily increasing, and the necessity for combined action and representation among scientific men themselves is being more and more felt, the popularisation of science becomes more important than ever, and every effort to gain these ends deserves a larger encouragement, for the most "practical man" will now soon be made to feel that Science dogs his every footstep, meets him at every turn, and twines itself round his life; nay, it may soon become evident that such a practical thing as a stagnation of trade may in some way be traced to the neglect of science.

Hence our endeavour in the future will be not only to make our journal a necessity in the Studies of the more thoughtful, and in our Schools, but a welcome visitor in the Homes of all who care for aught that is beautiful and true in the world around them.

EDITOR

THE VELOCITY OF THOUGHT

"As quick as thought" is a common proverb, and probably not a few persons feel inclined to regard the speed of mental operations as beyond our powers of measurement. Apart, however, from those minds which take their owners so long in making up because they are so great, rough experience clearly shows that ordinary thinking does take time; and as soon as mental processes were brought to work in connection with delicate instruments and exact calculations, it became obvious that the time they consumed was a matter for serious consideration. A well-known instance of this is the "personal equation" of the astronomers. When a person watching the movement of a star, makes a signal the instant he sees it, or the instant it seems to him to cross a certain line, it is found that a definite fraction of a second always elapses between the actual falling of the image of the star on the observer's eye, and the making of the signal—a fraction, moreover, varying somewhat with different observers, and with the same observer under differing mental conditions. Of late years considerable progress has been made towards an accurate knowledge of this mental time.

A typical bodily action, involving mental effort, may be regarded as made up of three terms; of sensations travelling towards the brain, of processes thereby set up within the brain, and of resultant motor impulses travelling from the brain towards the muscles which are about to be used. Our first task is to ascertain how much time is consumed in each of these terms; we may afterwards try to measure the velocity of the various stages and parts into which each term may be further subdivided.

The velocity of motor impulses is by far the simplest case of the three, and has already been made out pretty satisfactorily. We can assert, for instance, that in frogs a motor impulse, the message of the will to the muscle, travels at about the rate of 28 metres a second, while in man it moves at about 33 metres. The method by which this result is obtained may be described in its simplest form somewhat as follows:—

The muscle which in the frog corresponds to the calf of the leg, may be prepared with about two inches of its proper nerve still attached to it. If a galvanic current be brought to bear on the nerve close to the muscle, a motor impulse is set up in the nerve, and a contraction of the muscle follows. Between the exact moment when the current breaks into the nerve, and the exact moment when the muscle begins to contract, a certain time elapses. This time is measured in this way:—A blackened glass cylinder, made to revolve very rapidly, is fitted with two delicate levers, the points of which just touch the blackened surface at some little distance apart from each other. So long as the levers remain perfectly motionless, they trace on the revolving cylinder two parallel, horizontal, unbroken lines; and any movement of either is indicated at once by an upward (or downward) deviation from the horizontal line. These levers further are so arranged (as may readily be done) that the one lever is moved by the entrance of the very galvanic current which gives rise to the motor impulse in the nerve, and thus marks the beginning of that motor impulse; while the other is moved by the muscle directly this begins to contract, and thus marks the beginning of the muscular contraction. Taking note of the direction in which the cylinder is revolving, it is found that the mark of the setting-up of the motor impulse is always some little distance ahead of the mark of the muscular contraction; it only remains to be ascertained to what interval of time that distance of space on the cylinder corresponds. Did we know the actual rate at which the cylinder revolves this might be calculated, but an easier method is to bring a vibrating tuning-fork, of known pitch, to bear very lightly sideways on the cylinder, above or between the two levers. As the cylinder revolves, and the tuning-fork vibrates, the latter will mark on the former a horizontal line, made up of minute, uniform waves corresponding to the vibrations. In any given distance, as for instance in the distance between the two marks made by the levers, we may count the number of waves. These will give us the number of vibrations made by the tuning-fork in the interval; and knowing how many vibrations the tuning-fork makes in a second, we can easily tell to what fraction of a second the number of vibrations counted corresponds. Thus, if the tuning-fork vibrates 100 times a second, and in the interval between the marks of the two levers we count ten waves, we can tell that the time between the two marks, *i.e.* the time between the setting-up of the motor impulse and the beginning of the muscular contraction, was $\frac{1}{10}$ of a second.

Having ascertained this, the next step is to repeat the experiment exactly in the same way, except that the galvanic current is brought to bear upon the nerve, not close to the muscle, but as far off as possible at the furthest point of the two inches of nerve. The motor impulse has then to travel along the two inches of nerve before it reaches the point at which, in the former experiment, it was first set up.

On examination, it is found that the interval of time elapsing between the setting up of the motor impulse and the commencement of the muscular contraction is greater in this case than in the preceding. Suppose it is $\frac{2}{10}$ of a second—we infer from this that it took the motor impulse $\frac{1}{10}$ of a second to travel along the two inches of nerve: that is to say, the rate at which it travelled was one inch in $\frac{1}{20}$ of a second.

By observations of this kind it has been firmly established that motor impulses travel along the nerves of a frog at the rate of 28 metres a second, and by a very ingenious application of the same method to the arm of a living man, Helmholtz and Baxt have ascertained that the velocity of our own motor impulses is about 33 metres a second.* Speaking roughly this may be put down as about 100 feet in a second, a speed which is surpassed by many birds on the wing, which is nearly reached by the running of fleet quadrupeds, and even by man in the movements of his arm, and which is infinitely slower than the passage of a galvanic current. This is what we might expect from what we know of the complex nature of nervous action. When a nervous impulse, set up by the act of volition, or by any other means, travels along a nerve, at each step there are many molecular changes, not only electrical, but chemical, and the analogy of the transit is not so much with that of a simple galvanic current, as with that of a telegraphic message carried along a line almost made up of repeating stations. It has been found, moreover, that the velocity of the impulse depends, to some extent, on its intensity. Weak impulses, set up by slight causes of excitement, travel more slowly than strong ones.

The contraction of a muscle offers us an excellent objective sign of the motor impulse having arrived at its destination; and, all muscles behaving pretty much the same towards their exciting motor impulses, the results obtained by different observers show a remarkable agreement. With regard to the velocity of sensations or sensory impulses, the case is very different; here we have no objective sign of the sensation having reached the brain, and are consequently driven to roundabout methods of research. We may attack the problem in this way. Suppose that, say by a galvanic shock, an impression is made on the skin of the brow, and the person feeling it at once makes a signal by making or breaking a galvanic current. It is very easy to bring both currents into connection with a revolving cylinder and levers, so that we can estimate by means of a tuning-fork, as before, the time which elapses between the shock being given to the brow and the making of the signal. We shall then get the whole "physiological time," as it is called (a very bad name), taken up by the passage of the sensation from the brow to the brain, by the resulting cerebral action, including the starting of a volitional impulse, and by the passage of the impulse along the nerve of the arm and hand, together with the muscular contractions which make the signal. We may then repeat exactly as before, with the exception that the shock is applied to the foot, for instance, instead of the brow. When this is done, it is found that the whole physiological time is greater in the second case than in the first; but the chief difference to account for the longer time is, that in the first case the sensation of the shock travels along a short tract of nerve (from the brow to the brain), and in the second case through a longer tract (from the foot to the brain). We may conclude, then, that the excess of time is taken up by the transit of the sensation through the distance by which the sensory nerves of the foot exceed in length those of the brow. And from this we can calculate the rate at which the sensation moves.

Unfortunately, however, the results obtained by this method are by no means accordant; they vary as much as from 26 to 94 metres per second. Upon reflection, this is not to be wondered at. The skin is not equally sentient in all places, and the same shock might produce a weak shock (travelling more slowly) in one place, and a stronger one (travelling more quickly) in another.

Then, again, the mental actions involved in the making the signal may take place more readily in connection with sensations from certain parts of the body than from others. In fact, there are so many variables in the data for calculation that though the observations hitherto made seem to show that sensory impressions travel more rapidly than motor impulses (44 metres per second), we shall not greatly err if we consider the matter as yet undecided.

By a similar method of observation certain other conclusions have been arrived at, though the analysis of the particulars is not yet within our reach. Thus nearly all observers are agreed about the comparative amount of physiological time required for the sensations of sight, hearing, and touch. If, for instance, the impression to be signalled be an object seen, a sound heard, or a galvanic shock felt on the brow, while the same signal is made in all three cases, it is found that the physiological time is longest in the case of sight, shorter in the case of hearing, shortest of all in the case of touch. Between the appearance of the object seen (for instance, an electric spark) and the making of the signal, about $\frac{1}{5}$; between the sound and the signal, $\frac{1}{6}$; between the touch and signal, $\frac{1}{7}$ of a second, is found to intervene.

This general fact seems quite clear and settled; but if we ask ourselves the question, why is it so? where, in the case of light, for instance, does the delay take place? we meet at once with difficulties. The differences certainly cannot be accounted for by differences in length between the optic, auditory, and brow nerves. The retardation in the case of sight as compared with touch may take place in the retina during the conversion of the waves of light into visual impressions, or may be due to a specifically lower rate of conduction in the optic nerve, or may arise in the nervous centre itself through the sensations of light being imperfectly connected with the volitional mechanism in the brain put to work in the making of the signal. One observer (Wittich) has attempted to settle the first of these questions by stimulating the optic nerve, not by light, but directly by a galvanic current, and has found that the physiological time was thereby decidedly lessened; while conversely, by substituting a prick or pressure

* Quite recently M. Place has determined the rate to be 53 metres per second. This discordance is too great to be allowed to remain long unexplained, and we are very glad to hear that Helmholtz has repeated his experiments, employing a new method of experiment, the results of which we hope will soon be published.

on the skin for a galvanic shock, the physiological time of touch was lengthened. But there is one element, that of intensity (which we have every reason to think makes itself felt in sensory impressions, and especially in cerebral actions even more than in motor impulses), that disturbs all these calculations, and thus causes the matter to be left in considerable uncertainty. How can we, for instance, compare the intensity of vision with that either of hearing or of touch?

The sensory term, therefore, of a complete mental action is far less clearly understood than the motor term; and we may naturally conclude that the middle cerebral term is still less known. Nevertheless, here too it is possible to arrive at general results. We can, for instance, estimate the time required for the mental operation of deciding between two or more events, and of willing to act in accordance with the decision. Thus, if a galvanic shock be given to one foot, and the signal be made with the hand of the same side, a certain physiological time is consumed in the act. But if the apparatus be so arranged that the shock may be given to either foot, and it be required that the person experimenting, not knowing beforehand to which foot the shock is coming, must give the signal with the hand of the same side as the foot which receives the shock, a distinctly longer physiological time is found to be necessary. The difference between the two cases, which, according to Donders, amounts to $\frac{66}{1000}$, or about $\frac{1}{15}$ of a second, gives the time taken up in the mental act of recognising the side affected and choosing the side for the signal.

A similar method may be employed in reference to light. Thus we know the physiological time required for any one to make a signal on seeing a light. But Donders found that when matters were arranged so that a red light was to be signalled with the left hand and a white with the right, the observer not knowing which colour was about to be shown, an extension of the physiological time by $\frac{154}{1000}$ of a second was required for the additional mental labour. This of course was after a correction (amounting to $\frac{0}{1000}$ of a second) had been made for the greater facility in using the right hand.

The time thus taken up in recognising and willing, was reduced in some further observations of Donders, by the use of a more appropriate signal. The object looked for was a letter illuminated suddenly by an electric spark, and the observer had to call out the name of the letter, his cry being registered by a phonautograph, the revolving cylinder of which was also marked by the current giving rise to the electric spark.

When the observer had to choose between two letters, the physiological time was rather shorter than when the signal was made by the hand; but when a choice of five letters was presented, the time was lengthened, the duration of the mental act amounting in this case to $\frac{170}{1000}$ of a second.

When the exciting cause was a sound answered by a sound, the increase of the physiological time was much shortened. Thus, the choice between two sounds and the determination to answer required about $\frac{50}{1000}$ of a second; while, when the choice lay between five different sounds, $\frac{88}{1000}$ of a second was required. In these observations two persons sat before the phonautograph, one answering the other, while the voices of both were registered on the same revolving cylinder.

These observations may be regarded as the beginnings of a new line of inquiry, and it is obvious that by a proper combination of changes various mental factors may be eliminated and their duration ascertained. For instance, when one person utters a sound, the nature of which has been previously arranged, the time elapsing before the answer is given corresponds to the time required for simple recognition and volition. When, however, the first person has leave to utter any one, say of five, given sounds, and the second person to make answer by the same sound to any and every one of the five which he thus may hear, the mental process is much more complex. There is in this case first the perception and recognition of sound, then the bare volition towards an answer, and finally the choice and combination of certain motor impulses which are to be set going, in order that the appropriate sound may be made in answer. All this latter part of the cerebral labour may, however, be reduced to a minimum by arranging that though any one of five sounds may be given out, answer shall be made to a particular one only. The respondent then puts certain parts of his brain in communication with the origin of certain outgoing nerves; he assumes the attitude, physical and mental, of one about to utter the expected sound. To use a metaphor, all the trains are laid, and there is only need for the match to be applied. When he hears any of the four sounds other than the one he has to answer, he has only to remain quiet. The mental labour actually employed when the sound at last is heard is limited almost to a recognition of the sound, and the rise of what we may venture to call a bare volitional impulse. When this is done, the time is very considerably shortened. In this way Donders found, as a mean of numerous observations, that the second of these cases required $\frac{75}{1000}$ of a second, and the third only $\frac{39}{1000}$ over and above the first. That is to say, while the complex act of recognition, rise of volitional impulse, and inauguration of an actual volition, with the setting free of co-ordinated motor impulses, took $\frac{75}{1000}$ of a second, the simple recognition and rise of volitional impulse took $\frac{39}{1000}$ only. We infer, therefore, that the full inauguration of the volition took $\frac{75-39}{1000}=\frac{36}{1000}$. In rough language, it took $\frac{1}{28}$ of a second to think, and rather less to will.

We may fairly expect interesting and curious results from a continuation of these researches. Two sources of error have, however, to be guarded against. One, and that most readily appreciated and cared for, refers to exactitude in the instruments employed; the other, far more dangerous and less readily borne in mind, is the danger of getting wrong in drawing averages from a number of exceedingly small and variable differences.

M. FOSTER

CHOICE AND CHANCE

Choice and Chance. By the Rev. Wm. Allen Whitworth, M.A., Fellow of St. John's College, Cambridge. 2nd ed. Enlarged. 1870. (Deighton, Bell & Co.)

WE should think that not a few copies of the first edition of this work must have been purchased under the impression that it was an interesting story; and it is surprising that so neat and suggestive a title had not been long ago appropriated by some needy novelist. This work, however, is a very able elementary treatise on those puzzling branches of mathematics which treat of combinations permutations, and probabilities. The earlier chapters are quite within the comprehension of a schoolboy with a moderate knowledge of arithmetic; the appendices, which treat of distributions, derangements, the disadvantage of gambling, and a proof of the Binomial Theorem, founded purely on the doctrine of combinations, require some knowledge of algebra in the reader. So great is the clearness with which Mr. Whitworth states and explains the problems throughout, that it is almost impossible to misunderstand him. The appendix in which the disadvantage of gambling is demonstrated is very interesting, and often novel; and his explanation of the Petersburg problem is the most satisfactory which we have met.

Our only regret concerning the work is that Mr. Whitworth has not attempted more. Though the doctrines of combinations and probabilities lie at the basis of all mathematical and physical science, their value is chiefly theoretical, and it is hardly likely that time can be spared for their study in a school education. Had Mr. Whitworth enlarged his work so as to make it a pretty complete handbook of the theory of probabilities, he would have performed a great service to science. It is strange how little attention has been paid at Cambridge to the theory of probabilities. If we except Mr. Todhunter's valuable history, and Mr. Airy's special work upon its application to observations, we cannot call to mind any recent separate work devoted to rendering the subject of probabilities accessible to students. Mr. De Morgan's article in the Encyclopædia Metropolitana, his excellent work in the Cabinet Cyclopædia, the Useful Knowledge Society's essay, Galloway's treatise, and the translations of Quetelet's work, are what we have to depend upon as introductions to the subject; but they are all twenty or thirty years old at least, and difficult to meet with. Mr. Venn's logic of chance, being purely metaphysical, is not to be counted. We wish that Mr. Whitworth, or some mathematician at once as able, and possessed of as clear a style of exposition, would fill this gap in mathematical literature by producing a student's handbook of probabilities, including the theory of errors, the method of least squares, &c., with some of the applications to practice.

W. S. JEVONS

OUR BOOK SHELF

F. Hoppe-Seyler. Handbuch der physiologischen u. pathologischen Analyse. Third edition. (Berlin, 1870.)

WHILST modern chemical literature is abundantly supplied with publications on the analysis of mineral substances, works on the methods of chemical investigation of the products of animal life are comparatively few. Physiological chemistry is still in its infancy. By far the greatest number of the substances occurring in the animal body have as yet to be discovered, and even those already known exhibit but in few instances such characteristic reactions as serve for their detection and quantitative estimation equal in reliability to those we find in mineral chemistry. But however incomplete the analytical methods of the physiological chemist may be, they are highly valuable, not merely from a scientific, but also from a practical point of view, inasmuch as they aid the physician in the detection of those important changes in the chemical composition of animal fluids and excreta, which almost invariably accompany certain forms of disease. The scientific man as well as the medical practitioner will, therefore, take an equal interest in the re-publication in an enlarged form of a work on the application of chemical analysis to physiology and pathology, which has proved very valuable in its former editions.

The "Handbook" of Mr. Hoppe-Seyler's is adapted to the use of the advanced medical student as well as of the physician. That part of the book treating on the analysis, properly speaking, of animal fluids, tissues, &c., is preceded by some very useful chapters on the employment of chemical and physical apparatus; on re-agents and the mode of ascertaining the purity of the same; and on the composition, the properties, and detection of inorganic and organic chemical compounds occurring in the animal body. The great attention paid to the optical properties, of the various substances occurring in the body to the methods of their examination by means of the polariscope and spectroscope, forms a very remarkable and important feature of the book. Physiological chemistry claims a large share of the results which natural science owes to the application of these instruments, and a more extensive use of optical methods of research will certainly lead to further important discoveries. The author does not include the analysis of gaseous products, nor does he give an account of the methods used for the detection of poisons. The detection of blood-spots on wood, cloth, &c., is treated in an appendix. A chromolithograph, representing the spectra of the alkali metals, the absorption bands of hæmoglobine, and various tables and engravings, contribute to the usefulness of the work.

B. FINKELSTEIN

Search for Winter Sunbeams in the Raviera, Corsica, Algiers, and Spain. With numerous illustrations. By Samuel S. Cox. (London: Sampson Low, Son, and Marston. New York: D. Appleton and Co.)

THIS interesting book will be welcome to those who are seeking to find a home in a sunnier clime than our own The author points out the beauties and the medicinal qualities of the south. In his preliminary chapter he explains the title, "Sunbeams," giving the functions of light, music of light, analogy between light and sound, speaking especially of the life-giving power of the golden sunbeam. Quoting Prof. Maury's thoughts on light, he says, "that the organs of the human ear are so ordered that they cannot comprehend colour any more than the eyes can see sounds; yet, that we may hear over again the song of the morning stars, for light has its gamut of music! The high notes vibrate with the violet of the spectrum, and the red extremity sounds the bass; and though the ear may not catch the song that the rose, lily, and violet sing, it may, for aught we know, be to the humming-bird the butterfly, and the bee, more enchanting than that which 'Prospero's Ariel' sung to the shipwrecked mariner."

The author rapidly describes the well-known winter resorts, Nice, Mentone (of which, with its lovely flowers and fruits, he draws a most inviting picture), Monaco, with its roulette table, myths, and beautiful scenery; then comes Corsica, its chief town, Ajaccio, being renowned as the birthplace of Napoleon. Many interesting facts are here given of his mother, Madame Letitia, with incidents of his boyhood. The author then proceeds to Africa, passing through Algiers, visits the Kabyle people and Arabs, giving a description of the Blidah orange orchards, Algerine desert, the magnificent cedars and oaks on Mount Atlas, the Arab and Moorish women, different interesting old tombs, mosaics, and inscriptions. Our author travels on to Spain and compares it with Algiers.

Arrived at Murcia he witnesses a bull-fight, then he visits the Alhambra with its graceful architecture; *en route* for Madrid he passes many curious towns and castles. The following is a description of one:—"A mist obscured the mountains above. That old Moorish castle near the hill of the Pharos is called the Alcazaba. Its Puerta de la Cava is renowned, if not in history, in legend, as the scene of the suicide of Count Julian's daughter, whose woes brought on the Moorish invasion, and whose Iliad has been sung in prose by Irving. This castle is hid under a veil, even as Irving dropped over its rigid outlines the drapery of his genius. . . . The mist lifts a little. We see a streak of sunlight on a bleak, bright mountain ahead of us. We pass by gardens of immense fig-trees. The mountains begin to shine white. We are in the vine-hills again. . . . Cactus, oleander, orange, and pomegranate—all these appear." He then passes through the Basque country, St. Sebastian, and Biarritz, which the author considers "the very pearl of a summer resort." The work is ended with a fable recorded by Ford: "When San Ferdinand captured Seville from the Moor and bore the conquest to heaven, the Virgin desired her champion to ask from the Supernal Power any favour for Spain. The King asked for a fine climate and sweet sun: they were conceded. For brave men and beautiful women: conceded. For oil, wine, and all the fruits and goods of this teeming earth. This request was granted. 'Then will it please the beauteous Queen of Heaven to grant unto Spain a good Government?' 'Nay, nay, that can never be. The angels would then desert heaven for Spain!'"

The book is plentifully interspersed with good illustrations.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Sources of the Nile

FROM Mr. Keith Johnston's communication to NATURE of the 14th April, it appears that he agrees with me in opinion—though quite independently of me and by a different process of reasoning—that the great river Kassabi, Kassavi, or Kasai, of South-Western Africa, instead of flowing to the north and north-west, as it has hitherto been shown to do in all maps, has its course north-eastward as far as about the meridian of 27°30′ east of Greenwich, where it is joined by the river system of the Chambeze. Such being the case, the only material question between us is with respect to the lower course of the united stream of the two rivers, which Mr. Johnston carries round by a sharp curve to the north-west and west, so as to join the Zairé or Congo river, whereas I regard it as continuing northwards, and uniting with the Albert Nyanza, so as to form the upper course of the Nile.

While thus disputing the claim of the Kassavi and Chambeze to be the head-streams of the Nile, Mr. Keith Johnston advocates the rival claim of "the feeders of Lake Liemba." I do not, however, understand him to mean that these rivers, four in number, are to be considered the head-streams of the main body of the Nile, or to be anything but tributaries of that river, as is, in fact, shown in the map accompanying his paper. It being upon this point that the whole difference between us really hinges, I beg to be allowed to offer the following observations on the subject.

Dr. Livingstone, the discoverer of Lake Liemba, describes it as lying at an elevation of 2,800 feet above the sea, on the northern slope of the Balungu upland, in a hollow with precipitous sides 2,000 feet down, and as going away in a river-like prolongation, two miles wide, N.N.W., to Tanganyika, of which he rightly considers it to be an arm; the difficulty with respect to the elevation of the latter having been removed by Mr. Findlay, who makes it to be 2,800 feet, or the same as that of Lake Liemba.

Captain Burton, the discoverer of Tanganyika, says respecting this great lake: "The general formation suggests, as in the case of the Dead Sea, the idea of a volcano of depression—not like the Nyanza or Ukerewe formed by the drainage of mountains. Judging from the eye, the walls of this basin rise in an almost continuous curtain, rarely waving and infracted, to 2,000 or 3,000 feet above the water-level;" from which description it is evident that Liemba and Tanganyika are portions of one continuous fissure or "crack" in the table-land, of which table-land the elevation is 5,000 feet, or perhaps more, above the ocean.—Dr. Livingstone says 4,000 to 6,000 feet, sloping towards the north and west, but he had not seen any part of it under 3,000 feet of altitude. Further, Lake Tanganyika is described by Dr. Livingstone as passing northwards, by a river named Loanda, into Lake Chowambe, which lake he identifies with Sir Samuel Baker's Albert Nyanza.

The last-named expanse of water was found by its discoverer to have an elevation of 2,720 feet above the ocean, with a precipitous cliff of 1,200 to 1,500 feet on the east shore, whilst on the opposite side the faint blue mountains rose about 7,000 feet above the water-level.

The Albert Nyanza is, however, in nowise a continuation of the system of which Liemba and Tangányika form parts; for whilst the direction of these two lakes is from north to south, or nearly so, the general bearing of the Albert Nyanza is from about north-east to south-west; so that, as is shown on Mr. Keith Johnston's map, the former joins the latter at an angle of 45°; whilst the main body of water extends probably a hundred miles beyond the junction, or to about the 28th meridian. And the Albert Nyanza does not terminate here; for, in the latitude of Karagwe, between 1° and 2° S., it was said by the natives to turn to the west, in which direction its extent was unknown even to Rumanika, the King of Karagwe.

Quite independently, then, of the question of the junction of the joint stream of the Kassavi and Chambeze with the Nile, there is this preliminary question, which I would propound for Mr. Keith Johnston's consideration and answer:—Where would he place, even if only conjecturally, the head of this unknown western extension of the Albert Nyanza?—or, in other words, where would he trace the western limits of the Upper Nile basin?

As regards his objection to "the northward wall-like continuation of the Mossamba mountains on the 20th meridian to beyond the equator," shown in my sketch-map of the Upper Nile basin, in Part xv. (for March 1st last) of the "Illustrated Travels," I must explain that the same is so marked merely conjecturally, and that I do not think of maintaining it against—I will not say proof—but any reasonable argument. In my former maps of 1849, 1859, and 1864, I placed the conjectural western limits of the basin of the river somewhere about that meridian on or near the equator, thence continuing to about 10° N. lat., where the line was made to curve inwards towards the valley of the river. When I found the Kassavi, which I look on as the head-stream of the Nile, actually rising in the Mossamba mountains, on about the meridian thus indicated, I naturally extended my conjectural limits of the basin of the river along the same meridian from the equator southwards. But I repeat that, beyond what we actually know, all the rest is purely conjectural. If there is reason to carry the limits of the basins of the rivers of the West Coast of Africa to the east of the 20th meridian, on the equator or even as far south as the fifth parallel of south latitude, I have nothing to object to it, except that care must be taken to leave sufficient space for the western flank of the basin of the River Nile.

And this brings me to what I regard as an insurmountable objection to Mr. Keith Johnston's hypothesis. By causing, as he does, the Kassavi and Chambeze, after their union on the meridian of 27° 30′, to make a curve round to the north-west and west, so as to form the main-stream of the Congo River, he actually brings the course of this supposed river within 150 miles of the south-western extremity of the Albert Nyanza, as laid down on his own map. But to enable him to do this, he must, in defiance of Sir Samuel Baker's authority, deny the great westerly extension of this immense body of water; and by closing it up in that direction he renders it merely a "back-water" to Tanganyika, as Captain Speke imagined it to be to his Victoria Nyanza, instead of its being the main-stream of the Nile. Mr. Keith Johnston evidently has misgivings on this head, for he says: "If, however, the Albert Nyanza prove to have a great south-westerly extension, this one difficulty would be removed,"—namely, the sole difficulty in the way of the junction of the Kassavi and Chambeze with the Nile, for which I contend.

The argument founded on the comparative levels of Lakes Moero and Tanganyika I fail to appreciate. If the upland, 2,000ft. below which Liemba and Tanganyika lie, has a general elevation of 5,000ft., the waters of Lake Moero, instead of passing as they do through the crack in the mountains of Rua, could not by any possibility unite with those of Tanganyika, except by means of a similar crack in the mountains forming the western side of the latter; unless, indeed, Moero were supposed to lie on the upper level, to which supposition Mr. Johnston's argument is diametrically opposed.

In support of my own argument that the united stream of the Kassavi and the Chambeze continues northwards to join the Nile, instead of turning round to the north-west and west to join the Congo, I have really nothing to add. My opponent himself carries the joint stream for me to within 150 miles of the known south-western extremity of the Albert Nyanza: it is for him to show how the two are to be prevented from uniting. But in doing so he must bear in mind that the waters of Ulenge, made by him to be the recipient of the Kassavi, as well as of the Chambeze, are said by some of Livingstone's native informants to flow N.N.W. into Chowambe or Albert Nyanza, and that for the westerly extension of this body of water we have the authority of Baker.

On the subject of the Congo I have little to say. If it should be found that north of the fifth parallel of south latitude the basin of that river requires to be carried further eastward than the 20th meridian, I see no objection to it. Only I am bound to remark, that I do not consider there is any warrant for representing the Congo as a river having a low alluvial valley extending some 500 or 600 miles inland. I have not examined the subject of this river very closely, but my impression is, that, like the other rivers of the West Coast of Africa south of the equator, the rise of the level of its bed is rapid, and that it becomes considerable within a short distance from the ocean; so that there would not be sufficient fall for the waters of Ulenge in 27°30′ E. long. to join it. And, further, I cannot but entertain the opinion that the volume of water of the Congo has been greatly over estimated; in support of which opinion I will cite the following passages, in pages 147 and 148, of Captain Tuckey's Narrative:—"At the further end of the banza we unexpectedly saw the fall almost under our feet, and were not less surprised than disappointed at finding, instead of a second Niagara, which the description of the natives and their horror of it had given us reason to expect, *a comparative brook bubbling over its stony bed* . . . . The principal idea that the fall creates is, that the quantity of water which flows over it is by no means equal to the volume of the river below it; and yet, as we know there is not at this season a tributary stream sufficient to turn a mill below the fall, we can hardly account for this volume, unless we suppose, as Dr. Smith suggests, the existence of subterranean communications or caverns filled with water." Does this look like the lower course of the supposed second great river of Africa, with a basin of which the area is estimated to measure 800,000 square miles?

On a reconsideration, then, of the whole subject, I see no reason whatever to go from the opinion I have expressed, that the rivers Kassavi and Chambeze unite to form the upper course of the Albert Nyanza; that is to say, the main stream of the Nile; and as the former of those two rivers has the more direct course, and its source is the most remote of all, it is entitled to the honour which I claim for it, of being the hitherto undiscovered head of the great river of Egypt.

Bekesbourne, April 22 CHARLES BEKE

P.S., April 26.—Since the foregoing was written, Mr. Keith Johnston has obligingly sent me a copy of his "Map of the Lake Region of Eastern Africa," with notes, just published, in which I find a categorical answer to my question respecting the western limits of the Upper Nile Basin. He traces them as coming from the south of Lake Liemba and its feeders, and running close along the western side of Tanganyika as far as its northern end, where he gives them a curve to the westward not more than sufficient to include the south-western of the Albert Nyanza, and thence continuing along the high mountains on the west side of that body of water, the westerly extension of which, reported by Baker, he ignores entirely. To these views I need not reiterate my objections. C. B.

Why is the Sky Blue?

CAN any of your readers inform me why the sky is blue? Is it that the predominant colour of sunlight being orange, the regions devoid of sunlight appear of the complementary colour? If so, the planets of Sirius and Vega would have a black sky, those of Betelgeux a green sky, while those of the double stars would have different coloured skies at different times, according to their position with respect to their two luminaries. Or again, is the blueness merely the colour of our atmosphere, as Prof. Tyndall's experiments have led some to believe? In favour of the former explanation, is the fact that the maximum intensity of the light of the solar spectrum is in the orange, and indeed that the sun *looks* orange, and if we close our eyes after gazing a moment at him when high up in the sky, we see a blue image. When the sun is low, his colour changes from orange to red, and this would explain the green tints so often seen in the cloudless parts of the sky at sunset. Possibly Mr. Glaisher, who has seen the sky through a thinner stratum of air than most of us, could help us to a solution. H. A. N.

Hampstead, April 24

Curious Facts in Molecular Physics

SOME of the phenomena of photography present features of a very curious nature, yet seem to be very little known to philosophers who devote their time to researches in molecular physics. For instance, when a glass plate coated with collodion containing an iodide—say iodide of cadmium—is dipped into a "bath" solution of nitrate of silver, strength twenty-five grains to the ounce, in from three to four minutes a good dense precipitate of yellow iodide of silver is formed in the spongy collodion film, and the plate is ready for photographic use. But, let a plate be covered with collodion containing bromide of cadmium, (ten grains to the ounce) instead of iodide of cadmium, an immersion of ten or fifteen minutes is necessary to obtain a good film of bromide of silver, though the collodion skin upon the glass surface is only of the same thickness as in the former instance, and not only is this much longer immersion necessary, but the nitrate of silver solution must be increased in strength to about sixty grains to the ounce to get the best results. When the strength of the nitrate of silver is only twenty-five grains to the ounce, the bromide of silver forms more on the surface of the collodion than within it, and sometimes breaks away in scales from the collodion, and falls to the bottom of the bath.

Lastly, let chloride of cadmium be used instead of the bromide in the collodion, the strength of the nitrate of silver must be increased to about one hundred grains to the ounce of water, and an immersion of thirty or forty-five minutes is necessary to get a good photographic precipitate of chloride of silver. In this case, when a weak nitrate of silver solution is used, an uneven precipitate is formed upon the plate, and the tendency to burst out of film in scales is seen as in the former instance.

The three kinds of films just described vary in their photographic properties. The iodide of silver film requires the shortest exposure in the camera to produce a good picture, the bromide of silver film requires a longer exposure, and the chloride of silver film requires the most prolonged exposure to light of all.

Again, the iodide of silver film is more liable than the others to spots and markings, when there are particles of dust or other impurities on the glass plate or in the solution used; bromide of silver is not nearly so delicately sensitive to such disturbing influences; the chloride of silver film is even less sensitive in this respect than the bromide surface.

The reason of the differences of time of exposure just mentioned may possibly be accounted for on the supposition that chlorine binds itself to silver with more force than is exerted by bromine, and that the atom of bromine clings to the atom of silver with more tenacity than iodine clings to the metal. Hence the waves of light have more work to do in beating chlorine from silver than in beating iodine from silver. One very beautiful experiment, first made by Mr. M. Carey Lea, of Philadelphia, tends to prove that light will widen the distance between the hypothetical swinging atoms of iodine and silver, and that in darkness the atoms, with their attraction for each other thus partially overcome, will gradually fall together again. He prepared a film of absolutely pure dry iodide of silver, upon a glass plate, which film in the process of preparation had not been allowed to come into contact with the slightest trace of organic matter, in the washing water, or by any other means. On exposing such a film to light under a negative, and then applying what is known as the "alkaline developer," a picture came out; but if instead of developing the picture, the exposed plate were allowed to rest a day or two in the dark, the latent image died out, the film, so far as is known, returned to its primitive condition, and on exposure under another negative, a picture from it could be brought out, with no trace of the image impressed for a time through the first negative. The alkaline developer seems to "drink up" the iodine where its cohesion to the silver is loosened, thereby leaving a dark deposit of metallic silver, but where the light has not somewhat beaten the atoms asunder, the developer has no action, unless its strength be increased till it blackens the whole plate, whether the light has acted upon the film or not. The alkaline developer consists of a weak solution of pyrogallic acid, rendered alkaline by the addition of a few drops of carbonate of soda.

This is but one instance among many of the facilities offered by photographic phenomena to those who are trying to peer into the penumbral philosophical region of molecular physics.

WILLIAM H. HARRISON

SIR EDWARD SABINE'S CONVERSAZIONE

WHATEVER may be said by those to whom the grapes are sour, the gathering which met at Burlington House on April 23 to greet the President of the Royal Society, under animating circumstances, can hardly fail of beneficial results, whether regarded from the social, the moral, or the scientific point of view. It would not be easy to devise a happier way of bringing novelties at once under practical criticism—of making the outliers of science acquainted with the centre, of enabling investigators to compare operations and discuss facts and speculations, and of giving occasion for renewal of intercourse and removal of misunderstandings.

As usual, the range of articles exhibited was wide enough to include different branches of science, from astronomy to natural history, and from electro-magnetism to physiology, with achievements of fine art, and of arts mechanical. In an exhausted hydrogen tube placed across the poles of an electro-magnet, Mr. C. F. Varley produced a beautiful luminous arc, the dimensions of which he could vary at pleasure by a change in the size of the negative pole, and occasion a change of direction by a slight elevation of one end of the tube.

Spectroscopy, as we have more than once had occasion to record, owes much to the constructive skill of Mr. Browning. We shall return, on a future occasion, to his new automatic spectroscope.

Mr. C. W. Siemens's Electrical Resistance Pyrometer well maintains the reputation of the inventor for application of philosophical principles to mechanical uses. It is the very salamander of pyrometers, and will measure the temperature of the most highly heated fiery furnace; which must render it indispensable in operations where intense heat is required, and to all experimentalists who know the imperfections of the pyrometer in ordinary use. The construction of the new instrument is based on the physical fact that the resistance of pure metals to the electric current increases with increase of temperature in a simple absolute ratio. A platinum wire of known resistance is coiled upon a small cylinder of fireclay, and is covered by a tube of the same metal, which protects the wire from the destructive action of flame, without preventing access of heat. Thus constructed, the pyrometer is placed in the furnace, and is connected by wires with a Daniell's battery of two cells, and with a compact Resistance-measurer, specially devised by Mr. Siemens, on which the observer makes observations at his ease. As the fire burns, the electrical resistance of the platinum coil rapidly increases, communicates its progress to the measurer on which the indications of temperature may be read off as entirely trustworthy, even up to the melting point of platinum. The importance of such an instrument as this cannot fail to be recognised by practical men, whether among natural philosophers or workers in the pyrotechnic arts; and, for our part, we cordially welcome this new pyrometer as a logical sequence from the inventor of the regenerative gas-furnace with its fierce heat-producing capabilities.

Mr. Jerry Barrett, who relieves his hours at the easel with natural philosophy, exhibited an auxiliary air-pump, which appears to produce that essential desideratum, a perfect Torricellian vacuum. To an ordinary air-pump he attaches an air-chamber or reservoir, and, communicating therewith, two cylindrical glass vessels charged with mercury, and connected by a V tube. On working the pump the pressure of the air in the lower vessels compels the mercury to rise and fill the upper one, in which an ingeniously contrived platinum valve plays an important part. By continuing the process of filling and emptying (the details of which are not easy to describe), the desired vacuum is eventually obtained, and the exhausted tube on the top of the pump is ready for experiment. We learn that a well-known experimentalist was so favourably impressed by the capabilities of this pump that he intends to have a number of large tubes made for a series of experiments.

In these days of busy telegraphy, Mr. J. Parnell's new secondary battery is worth attention. It is so constructed as to be capable of a large amount of heavy work, having forty cells, each containing a pair of copper plates immersed in a solution of the impure carbonate of sodium, known in commerce as "soda." By this employment of an alkali, the electromotive force produced is supposed to depend on the electrolytic reduction of the sodium. The battery is arranged in ten compound cells of four couples each, and is charged by a small battery of five Grove cells, and after the connection has been established for a few seconds, a commutator of peculiar construction is brought into play, and excites the whole forty cells to activity. It is thought that a battery so constructed, which can be energised at pleasure by a brief communication with the small Grove, will be found of service in telegraphing through lines of great resistance.

Rear-Admiral Inglefield's contrivance for making the water in which a ship floats do the work of steering appeals to every Englishman, for are we not all interested in our navy, whether Royal or commercial? It is a contrivance which involves a large economy, for instead of a number of men labouring at two wheels, and with relieving tackles, it requires one small wheel only, and one man to steer the largest ship afloat; estimating roughly the pressure of the water as half a pound per square inch for every foot of the ship's draught. Admiral Inglefield admits the water through the bottom by a "Kingston valve" into a cylinder placed at the stern. The piston of this cylinder works a double-action force-pump, which sends the water to two hydraulic cylinders; these are connected with a tiller four feet in length, and thus, by movements of the small steering wheel, the ship is easily steered. Trials made with this apparatus on board the *Achilles*, one of the largest vessels in the navy, proved satisfactory; and in an improved form it is to be fitted to the *Fethi Bulend*, a corvette now building for the Turkish Government. Unfortunately for the visitors to the conversazione, the model exhibited, owing to lateness of delivery, could not be shown in work; but there was a skeleton of the corvette's stern, showing the position of the apparatus, and near it stood one of the small steering-wheels. By this and Admiral Inglefield's explanations, the naval men present could form an opinion of the new method, compare it with the existing method, and mark how surely the helm could be kept hard over during full speed, and how rapid and easy were its movements generally.

Mr. J. B. Rogers exhibited his life-saving apparatus, by which he has obtained the prize long offered by the Shipwrecked Mariners' Society, and furnished means of rescue, which, judging from the trials made near Portsmouth under authority of the Admiralty, are likely to render valuable service. With a mortar and a small charge of powder he throws out an anchor from the shore, and by means of the double rope thereto attached, a lifeboat can be hauled out through a heavy surf in weather when it would be impossible to launch her in the usual way; and with the further advantage that the hauling need not be done by the crew of the boat, who would consequently be fresh for their laborious task of rowing out to the ship in distress.

The Meteorological Office of the Board of Trade in carrying out their scheme of "ocean statistics," from which great advantage may be anticipated to navigation and to meteorological science, have constructed two charts, the value of which all whose business it is to go down to the sea in ships will appreciate. The wind chart is the first instalment of a series intended to show the best route for crossing the line in each month of the year. To facilitate reference, it is ruled in squares each representing a degree, with the direction and force of the prevailing winds. This is, we believe, the first attempt to show the *force* of the wind in a chart of this nature. The area embraced lies between the equator and 10°N. and 20° and 30°W., and contains the observations of five years for the month of November. When the other eleven months of the year are represented each by a chart, mariners will be able to choose a way across "the Doldrums" where they may be likely to find the most favourable winds and currents. From this it will be understood that the current chart is constructed in a similar style.

Principal Dawson, of M'Gill College, Montreal, who has just arrived with a fine collection of fossils, could not have desired a better opportunity for exhibiting them than was afforded by the conversazione. There, while showing his specimens to the *élite* of the scientific world, he could talk to them about the geological survey of Canada, and the Peninsula of Gaspé, with its cliffs of "Upper Silurian," 600 feet in height, its "Devonian sandstones" and "lower carboniferous deposits, and its arched rocks forming magnificent coast scenery. Among those fossils are two large tree-stems, *Protaxites Logani*, a species of *Psilophyton*, and a *Cyclostigma*, the latter a genus previously met with nowhere but in the Devonian rocks of Ireland. Other kinds include *Cordaites*, *Psaronius*, *Antholithes*, *Asterophyllites*, and a variety of ferns; and occurring in the animal remains, we find *Cephalaspis*, the first of the kind yet found in America, and *Machairacanthus*, and other large fishes. As Dr. Dawson is to read a paper on these important fossils at the Royal Society this evening, we may hope to see their story told in due time with suitable illustrations in the "Philosophical Transactions."

Dr. Carpenter exhibited with microscopes, with the actual specimens, and with a considerable breadth of well-executed diagrams, some of his treasures from the "deep, deep sea." In friendly neighbourhood, Prof. Tennant showed fossil specimens of some of the same creatures. And not far distant were hung Lieut. Palmer's clever drawings of living animals from the surface of the sea, captured in the China Sea, the Indian Ocean, and the Atlantic. These drawings testify to Lieut. Palmer's skill and industry. The animals are represented life-size and in their natural colours. Among them we observed the *Globigerina*, which may, perhaps, be taken as evidence that this creature does not, as some have supposed, exclusively inhabit the bottom of the sea. Considering that there is always room for natural history researches, the Admiralty should be able to find such employment for Lieut. Palmer as would exercise his artistic faculty and his habit of observation.

We are far from having exhausted the subject, but we must close here. Need we pause to draw a moral, or to point out that in such a conversazione as we have attempted to describe there is a tangible gain to science? It is well for inventors and experimentalists that they should hear what contemporaries say of their schemes and experiments, and much can be said and done with advantage amid the free talk of a general gathering which could not be permitted in the formal meeting of a scientific society. Let proper discrimination be used in the selection of articles for exhibition : science will then continue to benefit by soirées.

RECENT ACCESSIONS TO THE ZOOLOGICAL SOCIETY'S GARDENS

THE collection of living animals belonging to the Zoological Society of London and kept in their gardens in the Regent's Park contains, as most of the readers of NATURE are probably aware, by far the largest and most nearly complete living series of representatives of the various classes of Vertebrate animals that has ever been brought together in one spot. Great as the exertions that have been made of late years in some of the corresponding establishments on the Continent, the sister societies have never succeeded in rivalling the English collection as a whole, although they have occasionally bid fair to surpass it in some particular point.

The whole number of animals in the Zoological Society's Gardens usually somewhat exceeds two thousand—on the first of January last it was 2,031—consisting of 598 mammals, 1,245 birds, and 170 reptiles and batrachians, besides the fishes in the aquarium, which do not appear to be included in the annual census. Constant additions are made to the series, not only by purchase, but also by gifts of correspondents in every part of the world, and by exchange with the continental establishments. By these means the collection is kept up to its normal standard—the death-rate, as in all living zoological collections, being, in spite of every care and precaution, extremely heavy. During the past month of March 90 additions are recorded in the Society's register as having been made to the Menagerie. 33 of these were by gift, 33 by purchase, 4 by exchange, 5 by birth, and 15 were animals received "on deposit." The decrease during the same period by death and departures was 96, showing a total loss to the collection during the month of 6 individuals.

The most noticeable amongst the acquisitions to the Menagerie in March last were the four following :—

(1). Examples of two very fine new pheasants, recently discovered in Upper Assam by the well-known Indian ornithologist, Dr. J. C. Jerdon, and named by him *Lophophorus sclateri*, and *Ceriornis blythii.* These birds are both of very great interest, not only as being brilliant additions to the two magnificent groups to which they belong, but also as being *typical* specimens, *i.e.*, the identical specimens upon which Dr. Jerdon has founded these two species.

The "Monaul," or Impeyan pheasant of the southern slopes of the Himalaya, is one of the best known of Indian game-birds, and at the same time one of the most magnificently-coloured birds of British India, insomuch that Mr. Gould has chosen it as the representative bird for the cover of the numbers of his great work on the "Birds of Asia." For many years this bird was believed to stand quite alone, and to be the sole existing representative of the genus *Lophophorus.* A short time ago, however, Monsignor Chauveau, titular Bishop of Lhassa, who has recently found it necessary to retire from his Tibetan diocese into the confines of China, sent home from *Ta-tsien-lieu*, in the western part of the province of Sechuen, where he has taken up his abode, a collection of birds, amongst which were a pair of a very fine new species of Impeyan pheasant. These specimens, after being named in France *Lophophorus Lhuysi*, in compliment to M. Drouyn de Lhuys, the Minister of Foreign Affairs, whom we suppose the describer was anxious, for some good reason, to propitiate, passed into the collection of the British Museum, where they may be now seen in the Ornithological Gallery. It was thus proved that a second Impeyan pheasant is found on the northern slopes of the great central range of Asia, where it doubtless occupies a corresponding elevation and fulfils similar functions in the economy of nature to the well-known bird of the Indian Himalayas.

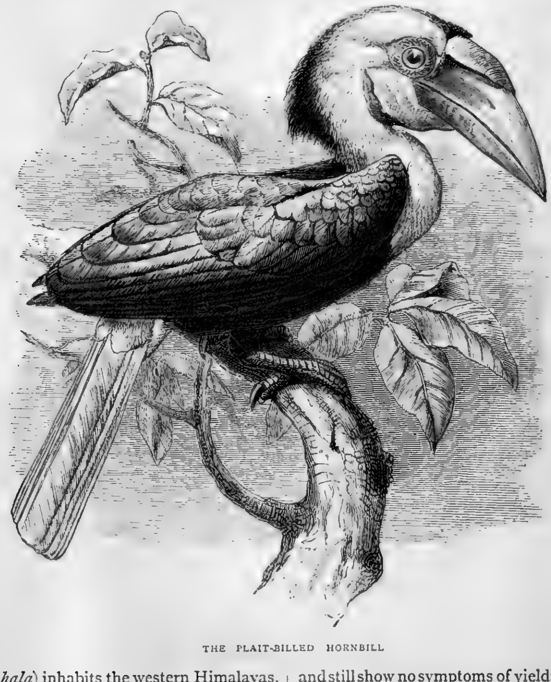
The discovery of the present bird by Dr. Jerdon, which, although somewhat different in certain details of structure from the two former, belongs strictly to the same genus, serves to further prove to us how much still remains to be done in zoological discovery, even amongst what are generally supposed to be the best-known divisions of the Vertebrata. Being crestless, Sclater's Impeyan, which has been named by Dr. Jerdon after the secretary of the Zoological Society of London, renders the old generic term *lophophorus* less applicable to the group. But in other points it does not materially differ, and at any rate is sufficiently near the common Impeyan to induce the only known individual of Sclater's Impeyan now in the Zoological Society's gardens to be quite ready to associate with a female of the latter which had been placed along with him.

Dr. Jerdon discovered this new bird during his residence at Shillong, a new sanitarium recently opened on the Khasya hills. The single example known was obtained from the Mishmees, a wild tribe which inhabits the hills of Upper Assam, by Major Montagu, of the Bengal Staff Corps, who, on being informed of the value of his acquisition, most liberally presented this unique specimen to the Zoological Society.

The new Tragopan which arrived in the Society's Gardens along with the last named bird, is hardly of less interest to the naturalist, and to the general observer a much more brilliant species in colour. It is likewise a gift of Major Montagu to the Society, having been obtained by him in the same district as the new Impeyan. The two Tragopans or "Argus Pheasants," as they are usually termed by Indian sportsmen, one of which (*Ceriornis melanocephala*) inhabits the western Himalayas, and the other (*C. satyra*) the Himalayas of Nipal and Sikim, have long been known as among the most splendid forms of the Gallinaceous order. The present bird, which has been named by Dr. Jerdon *Ceriornis blythii*, after one of the most distinguished of Indian naturalists, forms a third Indian species of the genus. There are likewise two Chinese Tragopans known—making in all five members of the group. Of one of these latter—Temminck's Tragopan (*C. temminckii*)—there are several pairs now in the Zoological Society's Gardens, and both this and the *Ceriornis satyra* have bred there in former years.

(2). Four young Hornbills belonging to three species (*Buceros bicornis*, *B. plicatus*, and *B. gracilis*), received March 18th.

A few years ago it was supposed to be impossible to keep alive in this country members of the great fruit-eating families of the Old-world and New-world Tropics—such as the Hornbills (*Bucerotidæ*), the Cotingas (*Cotingidæ*,) and others. Continued experience has, however, shown that the difficulties, formerly supposed to be insuperable, may be overcome by careful attention to diet and other matters, and in the case of the Hornbills the Zoological Society has succeeded in a very remarkable degree, some four or five of the finest species of the group having been successfully introduced into their aviaries, and kept in excellent health and condition. The most remarkable representatives of this group in the Society's Gardens at the present moment are, perhaps, the great Concave-casqued Hornbills (*Buceros bicornis*). A pair of these fine birds have inhabited one of the compartments of the large Eastern Aviary ever since the summer of 1864, and still show no symptoms of yielding to the inclemencies of the English climate. There are, indeed, great hopes of these birds breeding here, in which case the British public might have an opportunity of becoming acquainted with the very singular manners and customs of the Hornbills during the breeding season. No sooner has the hen commenced the labour of incubation, say several trustworthy observers on this subject, than the male walls up the hole in the hollow tree in which the hen is sitting on her eggs, until there is only room for the point of her bill to protrude, so that until her young birds are hatched she remains confined to her nest, and is in the meantime assiduously fed by her mate, who devotes himself entirely to this object. This habit has been testified to not only by Tickell, Layard, and other Indian naturalists concerning some of the Asiatic species, but is also spoken of by Dr. Livingstone



THE PLAIT-BILLED HORNBILL

in the case of Hornbills met with during his African explorations, and there appears to be no doubt of its authenticity. In Sumatra, in 1862, Mr. Wallace heard the same story from his hunters, and was taken to see a nest of the Concave-casqued Hornbill, in which, after the male bird had been shot while in the act of feeding its mate, the female was discovered walled up. "With great difficulty," Mr. Wallace tells us, "I persuaded some natives to climb up the tree, and bring me the bird. This they did, alive, and along with it a young one, apparently not many days old, and a most remarkable object. It was about the size of a half-grown duckling, but so flabby and semi-transparent as to resemble a bladder of jelly, furnished with head, legs, and rudimentary wings, but with not a sign of a feather, except a few lines of points indicating where they would come."

It would be certainly very delightful to be able to witness this imprisoning process in the Zoological Society's Gardens, and a fine moral lesson would at the same time be administered to such of the British matrons as are in the habit of running about neglecting their infant children.

Of the four Hornbills last received, one only belongs to the large species I have just spoken of. Two are the opposite sexes of a rather smaller bird, the Plait-billed Hornbill (*B. plicatus*), which is found in the Burmese peninsula, Sumatra and Java. The male, as in many other species, has the head and neck white or pale rufous, while the female these parts are black, like the rest of the body. It will be also remarked that the colour of the naked skin of the throat is not alike in the two sexes. The fourth and smallest bird is a female of the Slender Hornbill (*Buceros gracilis.*) Neither of these two last-named species have been previously exhibited in the Society's collection, which now contains twelve Hornbills of eight different species.

THE BURROWING OWL

(3.) Four Burrowing Owls (*Pholeoptynx cunicularia*), presented by George Wilks, Esq., C.M.Z.S., of Buenos Ayres. The Burrowing Owl is an American species of Day-Owl, well-known for its abnormal habits, and widely distributed in the New World. In the prairies of the far West, it lives in the "villages" of the Prairie-dog (*Arctomys ludovicianus*), residing in the forsaken burrows. "The burrow selected," says the well-known naturalist, Audubon, "is usually at the foot of a wormwood-bush (*Artemisia*), upon the summit of which the owl often perches, and stands for a considerable while. On being approached they utter a low chattering sound, start, and skim along the plain for a considerable distance. When winged they make for the nearest burrow, and when once within it, it is impossible to dislodge them." It is commonly said that rattlesnakes are likewise abundant in these "Prairie-dog villages," and that the beast, bird, and reptile, may not unfrequently be seen here in harmonious juxtaposition. In the pampas of South America, this little owl associates with another Burrowing rodent, which lives in communities in a similar manner to the Prairie-dog. This is the Vizcacha (*Lagostomus trichodactylus*). During the open day, Mr. Darwin tells us, but more especially in the evening, these owls may be seen in the pampas of the Argentine Republic in every direction, standing by pairs on the hillock next to their hole. If disturbed, they either retreat under-ground, or move with an undulatory flight to a short distance, and then turning round, steadily gaze at their pursuer.

The Burrowing Owl is, however, perfectly capable of making its own burrow, as Mr. Darwin tells us it always does where the Vizcacha is not found, and as it has done in the Zoological Society's Gardens. The first individual of this species which was received in 1868 from the same donor, was no sooner placed in a cage with a sandy floor than, "true to its habits, it excavated a hole in the soil at the bottom, into which it always retreated when threatened." The same habit may be witnessed on alarming the specimens of this bird now in the Society's gardens, although the burrow in the present instance has been, at all events partially, made artificially for their use.

(4.) An example of a rather rare Antelope from Western Africa—the Woodloving Antelope (*Cephalophus sylvicultrix*)—received in exchange March 24th. This is a representative of a group of Antelopes of small size which are found only in tropical or subtropical Africa, and are peculiar for having a little tuft of hair between their horns, as their generic name imports. Some eighteen or twenty species of this genus are known to science, and several of them are usually represented in the Zoological Society's collection. But the present animal, which is well marked by its white dorsal streak, has not been previously received alive by the Society. P. L. SCLATER

NOVEL TELEGRAPHY—ELECTRIFICATION OF AN ISLAND

A CURIOUS discovery has been made by Mr. Gott, the superintendent of the French company's telegraph station at the little island of St. Pierre Miquelon. There are two telegraph stations on the island. One, worked in connection with the Anglo-American company's lines by an American company, receives messages from Newfoundland and sends them on to Sydney, using for the latter purpose a powerful battery and the ordinary Morse signals.

The second station is worked by the French Transatlantic Company, and is furnished with exceedingly delicate receiving instruments, the invention of Sir William Thomson, and used to receive messages from Brest and Duxbury. These very sensitive instruments were found to be seriously affected by earth-currents; *i.e.*, currents depending on some rapid changes in the electrical condition of the island; these numerous changes caused currents to flow in and out of the French company's cables, interfering very much with the currents indicating true signals. This phenomenon is not an uncommon one, and the inconvenience was removed by laying an insulated wire about three miles long back from the station to the sea, in which a large metal plate was immersed; this plate is used in practice as the earth of the St. Pierre station, the changes in the electrical condition or potential of the sea being small and slow, in comparison with those of the dry rocky soil of St. Pierre. After this had been done, it was found that part of the so-called earth-currents had been due to the signals sent by the American company into their own lines, for when the delicate receiving instrument was placed between the earth at the French station and the earth at the sea, so as to be in circuit with the three miles of insulated wire, the messages sent by the rival company were clearly indicated, so clearly indeed, that they have been automatically recorded by Sir William Thomson's syphon recorder. Annexed is a facsimile of a small part of the message concerning the loss of the steamship Oneida, stolen in this manner.

It must be clearly understood that the American lines come nowhere into contact, or even into the neighbourhood of the French line. The two stations are several hundred yards apart, and yet messages sent at one station are distinctly read at the other station; the only connection between the two being through the earth; and it is quite clear that they would be so received and read at fifty stations in the neighbourhood all at once. The explanation is obvious enough: the potential of the ground in the neighbourhood of the stations is alternately raised and lowered by the powerful battery used to send the American signals. The potential of the sea at the other end of the short insulated line remains almost if not wholly unaffected by these, and thus the island acts like a sort of great Leyden jar, continually charged by the American battery, and discharged in part through the short insulated French line. Each time the American operator depresses his sending key, he not only sends a current through his lines, but electrifies the whole island, and this electrification is detected and recorded by the rival company's instruments.

No similar experiment could be made in the neighbourhood of a station from which many simultaneous signals were being sent; but it is perfectly clear that unless special precautions are taken at isolated stations, an inquisitive neighbour owning a short insulated wire might steal all messages without making any connection between his instrument and the cable or land line. Stealing messages by attaching an instrument to the line was a familiar incident in the American War; but now messages may be stolen with perfect secrecy by persons who nowhere come within a quarter of a mile of the line. Luckily, the remedy is simple enough. All owners of important isolated stations should use earth-plates at sea, and at sea only. This plan was devised by Mr. C. Varley many years ago to eliminate what we may term natural earth-currents, and now it should be used to avoid the production of artificial earth-currents which may be improperly made use of.

FLEEMING JENKIN

NOTES

WE regret to hear that Baron Liebig is very ill.

WE are informed that Messrs. Lyon Playfair, C.B., M.P., B. Samuelson, M.P., and Dr. W. A. Miller, will probably be among the members of the Royal Commission to inquire into the Present State of Science in this country.

PRINCIPAL DAWSON, of Montreal, who is now on a visit to this country, will deliver the Bakerian Lecture to-night before the Royal Society. The subject is the Pre-carboniferous Flora of North Eastern America. The opportunity of listening to so eminent a geologist on a subject which he has made especially his own, will doubtless draw together a large assembly of our men of science anxious to do honour to their distinguished *confrère*.

THE following gentlemen have been appointed by the University of London examiners and assistant examiners for 1870-

1871 in the various branches of science:—Logic and Moral Philosophy: Rev. Mark Pattison, B.D., and Prof. G. Croom Robertson, M.A. Political Economy: Prof. W. Stanley Jevons, M.A., and Prof. T. E. Cliffe Leslie, LL.B. Mathematics and Natural Philosophy: Prof. H. J. S. Smith, M.A., F.R.S., and Prof. Sylvester, M.A., F.R.S. Experimental Philosophy: Prof. W. G. Adams, M.A., and Prof. G. Carey Foster, B.A., F.R.S. Chemistry: Dr. Matthiessen, F.R.S., and Prof. Odling, M.B., F.R.S. Botany and Vegetable Physiology: Joseph Dalton Hooker, M.D., LL.D., F.R.S., and Thomas Thomson, M.D., F.R.S. Geology and Palæontology: Prof. Duncan, M.B., F.R.S., and Prof. Morris, F.G.S. Practice of Medicine: John Syer Bristowe, M.D., and Prof. J. Russell Reynolds, M.D., F.R.S. Surgery: Prof. John Birkett, F.R.C.S., and F. Le Gros Clark, F.R.C.S. Anatomy: Prof. William Turner, M.B., F.R.S.E., and Prof. John Wood, F.R.C.S. Physiology, Comparative Anatomy, and Zoology: Michael Foster, M.D., B.A., and Henry Power, M.B. Obstetric Medicine: Robert Barnes, M.D., and Prof. W. H. Graily Hewitt, M.D. Materia Medica and Pharmaceutical Chemistry: Thomas R. Fraser, M.D., F.R.S.E., and Prof. Alfred Baring Garrod, M.D., F.R.S. Forensic Medicine: E. Headlam Greenhow, M.D., and Thomas Stevenson, M.D.

PROFESSOR AGASSIZ is still seriously ill.

WE are rejoiced to hear that M. Janssen is to be provided with instruments wherewith to continue his observations on the sun by means of the new method. This was announced at the last meeting of the Paris Academy by M. Faye, who remarked: "El quelques mois il livrera à la Science cent fois plus de données précieuses que les astronomes n' auraient pu en recueillir, avant lui, par l'observation ordinaire des eclipses totales d'une vingtaine de siècles."

THE number of entries for the Examination for Women at the London University, which takes place during the current week, is 17, against 9 last year. Of these, 12 will be examined in London, and 5 at Cheltenham.

DR. A. VOELCKER and Mr. H. M. Jenkins, Secretary to the Royal Agricultural Society, reprint, from the Journal of the Society, a Report on the Agriculture of Belgium, containing much valuable information on its soil and climate, geological features, modes of agriculture, and rural economy.

"THE Body and its Health, a Book for Primary Schools," by E. D. Mapother, M.D., is a little elementary book on human physiology, prepared with greater care and attention to accuracy han is usually the case with primary scientific hand-books. It contains in a small space, and published at a low price, a mass of such information as ought to form a portion of the curriculum of all schools, both for boys and girls, and is illustrated by good woodcuts.

THE "Repertorium für Meteorologie," issued by the Imperial Academy of St. Petersburg, in the form of a 4to. volume, edited by Dr. H. Wild, Director of the Physical Central Observatory, contains a mass of tables respecting the meteorological phenomena of Russia, and a variety of other information.

WE have on our table the reports of several provincial scientific societies, and other papers of a like nature:—The Proceedings of the Berwickshire Naturalists' Club, for 1869; Transactions of the Norfolk and Norwich Naturalists' Society for 1869-70; the 37th Annual Report of the Royal Cornwall Polytechnic Society for 1869; and the Geology, Botany, and Zoology of the Neighbourhood of Alnwick, by George Tate, F.G.S. They all show the zeal with which the pursuit of natural history is followed in the provinces; these local societies have been the nursery of many a genuine naturalist who has rendered important service to the study of Nature.

AMONG the objects of interest exhibited at the soirée of the Linnean Society on the 27th ult., was a collection of plants made by Mr. W. W. Saunders, arranged in pairs; the plants forming each pair belonged to entirely different natural orders, but were so remarkably alike in the general form, and even in the marking of the foliage, as to be barely distinguishable even to a practised eye. One of the most strikingly "mimetic" pairs were a Conifer and a Selaginella, belonging to the two sub-kingdoms of flowering and flowerless plants.

ACCORDING to Mr. Kurtz, the Curator of the Herbarium of the Calcutta Botanical Gardens, the Andaman Islands are gradually sinking, the rate of subsidence being about one foot in a century. This inference is founded on the fact that trunks of trees still rooted in the ground may be seen in the water of the straits which separate the islands, belonging to species which never grow in mangrove swamps, but which are only found further inland. It is even possible to "trace in several places the stumps of the sunken trees in the sea, up to the state when the trees are just dying by the influence of the sea-water, and the subsequent change of the soil by the formation of the mangrove swamp." At the rate of subsidence indicated by Mr. Kurtz, a thousand years must elapse before the extensive convict establishment maintained on these islands will be in immediate danger of submersion.

IN a forthcoming number of his "Geographische Mittheilungen," by means of a map and a memoir, the geographer Petermann gives his rendering of the information contained in Dr. Livingstone's recent letters, taken in connection with the former travels of the Portuguese in Central South Africa. The new real geography of this map agrees remarkably well, in its general features, with a chart which lately appeared in this journal. There is, however, one main point of difference. A river named *Luvivi* was crossed by Pombeiro Baptista in his route to the Cazembe's town from that of the Muata Yanvo, and is distinctly stated by him to run into the Luapula, the river which is now known to unite Lakes Bangeweolo and Moero. Livingstone says that a large river named *Lufira* drains the western side of the great valley, and takes up the waters of Ulenge in the west of Tanganyika. On the foundation of the resemblance of these names—surely a very weak one in a region where duplicate river names are frequent—Dr. Petermann discards the Pombeiros statement, and uniting the Luviri with the Lufira, carries a great river through the midst of the country separating the valleys ruled over by the Muata Yanvo and the Cazembe, which all travellers here agree is a mountainous desert, and which the road joining these territories bends far southward to avoid. Again: The country of Usango is said by Livingstone to be on the east of the plateau which rises south of Tanganyika; on this map it is indicated to westward of that lake; and Lake Liemba, instead of being shown on the northern slope of that upland, is represented as lying in a valley directly continuing that of Tanganyika. The uncertainty as to the identity of the Chowambe Lake with the Albert Nyanza, and consequently of the union of Tanganyika with the Nile system, is considered too great to admit of any solution of the Nile problem as yet, and any attempt at this is characterised as plucking unripe fruit. This part also contains a very interesting account of a voyage by a Norwegian fisher named Captain E. H. Johannesen, who, in the summer of 1869, sailed completely round the island of Novaia Zemlia and through the Kara Sea. This gulf, believed till now to be constantly choked up by impenetrable ice-park, has been called the "ice-cellar" of the North Pole. In place of this, Johannesen found a mild atmosphere off the north-east of Novaia Zemlia, and throughout the whole Kara Gulf in July and August no ice was visible, but a heavy roll of the open sea came up from the south-east.

MR. B. WILLIAMSON, one of the Fellows of Trinity College, Dublin, is preparing a "Treatise on Mechanics," which will shortly be issued by the University Press.

Mr. James Glaisher has given two lectures for the "Sunday Lecture Society" on the evenings of April 24th and May 1st., on "The Balloon" and on "Rain." In the latter he gave an interesting account of how rain is derived and how measured ; some most carefully prepared tables were exhibited, together with diagrams and some excellent photographs of the varied forms of snow crystals. The lecture for May 8th will be by Mr. Henry Moody on "The Prevention of Infectious Diseases." The importance of this subject, in reference to the great object of the society, the social welfare of mankind, will be illustrated by the example of Bristol. From being one of the most unhealthy, Bristol has become one of the most healthy of cities. In the summer and autumn of 1832 the ravages there by cholera were enormous ; the deaths alone approaching to 1000 ! In 1866, on the contrary, when the poor at the East-end of London were dying by hundreds, the deaths in Bristol were but 26 ; and it will be pointed out that this vast difference has arisen from the precautions and general sanatory measures adopted by the inhabitants and authorities of the City of Bristol.

M. Quenault reports the discovery at Hauteville-sur-mer, near to a rock called Maulieu, of a bed of vegetable mould in which repose trunks of trees, still holding by their roots, along with a layer of turf. At high tide this bed is covered to the depth of about twelve inches. The oak alone has preserved its hardness, the other woods having become quite soft, but still preserving their colour and even their bark. He supposes the immersion to have taken place in the eighth century.

The ninth reunion of the learned societies of the Sorbonne took place on the 20th of April, when M. Le Verrier was appointed president, M. Milne-Edwards vice-president, and M. Blanchard, secretary of the Section of Sciences ; M. le Marquis de la Grange, president, M. Léon Renier, vice-president, and M. Chabouillet, secretary of the Section of Archæology ; M. Amédée Thierry, president, and M. Hippeau, secretary of the Section of History. M. Le Verrier stated that the lectures instituted at the Sorbonne, which have already been in existence ten years, have had already the most beneficial results ; they have formed bonds between the *savants* of France and of the other countries of Europe, and have contributed to raise scientific and literary labours to a higher and higher platform.

We have received Washington papers of the 13th, 14th, and 15th of April, containing a report of the 13th semi-annual session of the National Academy of Sciences, held in that city. The most important papers read were : "On the coming transits of Venus," by Prof. Simon Newcomb ; "On meridional arcs, measured in connection with the United States coast survey," by Mr. J. E. Hilgard ; "Craniological observations," by Dr. George Otis ; "The Northmen in Greenland," by Dr. Hayes ; "Considerations of the apparent inequalities of long periods in the moon's mean motion," by Prof. S. Newcomb ; "On the influence of the interior structure of the earth on precession and nutation," by Prof. J. G. Barnard ; "On a new classification of clouds," by Prof. Poey, of Havana ; "On fluctuations of the barometer," by Dr. B. F. Craig. Prof. Joseph Henry occupied the chair. We purpose giving abstracts of some of these pages on a future occasion.

A Natural History Society has recently been established at Winchester College ; and a Botanical Section has been formed in connection with the Hants and Winchester Scientific and Literary Society.

Mr. Llewellynn Jewitt has issued a prospectus of a proposed publication, by subscription, of an entirely new, large, and comprehensive history, topography, and genealogy of the county of Derby.

A paper appears in the last number of the "Proceedings of the Royal Society," by Dr. Herbert Davies, on the law which regulates the relative magnitude of the areas of the four orifices of the heart. He remarks that although to ordinary observation these orifices appear to exhibit no mutual relationship of size, there can be no doubt that an instrument so accurate in the adaptation of its valvular apparatus, and so exact in the working of its different parts, must reveal on close examination the existence of laws which not only determine the force required to be impressed upon the blood traversing its chambers, but also the relative sizes of these apertures to one another. On converting Dr. Peacock's measurements of the circumference of the several orifices into numbers representing these areas it is found that in the male the respective mean areas are

Tricuspid	$1\frac{3}{4}$ sq. inch.
Pulmonic	1 ,,
Mitral	$1\frac{1}{4}$,,
Aortic	$\frac{3}{4}$

and on pushing the inquiry further, it is found that there is a distinct law presiding over them which is discovered on comparing the ratios of the areas of corresponding orifices. Thus—

$$\frac{\text{Area of tricuspid}}{\text{Area of mitral}} = \frac{1.78}{1.27} = 1{\cdot}4 \text{ nearly}$$

$$\frac{\text{Area of pulmonic}}{\text{Area of aortic}} = \frac{1}{78} = 1{\cdot}3 \text{ nearly}$$

or in other words, the area of the tricuspid appears from these calculations to bear nearly the same relation to the area of the mitral, which the area of the pulmonic does to that of the aortic orifice ; *i.e.*, were the tricuspid, for example, twice the size of the mitral orifice in area, the pulmonic would be twice the size of the aortic orifice in area, the two ratios differing from each other only by one-tenth. The same law probably holds in the hearts of most animals, the areas of the four orifices bearing an exact mathematical relationship to each other, so that if the areas of any three of the openings be known, the area of the fourth orifice can be correctly calculated. A knowledge of this law, it is obvious, may prove of great importance in estimating the amount of contraction or dilatation of orifice which may be present in disease. Dr. Davis then proceeds to give the reasons for this arrangement, for which we must refer our readers to the original.

That the white corpuscles of the blood can pass through the walls of the blood-vessels is now admitted by so many observers, that it may fairly be regarded as an established fact. But the entrance of a solid body from the outside of the capillaries into their interior has, so far as we know, only been observed in one or two exceptional instances. Quite recently, however, M. Saviotti has published a paper in the *Centralblatt*, in which he describes the passage of entire pigment cells from the parenchyma of the web of the foot of the frog through the walls of the capillaries and smaller veins, into their lumen, where having arrived, they are swept away by the blood current as a phenomenon of common occurrence, and easily followed. To render this evident he excites local inflammation in the web by the application of a dilute (2 per cent.) solution of sulphuric acid. After the lapse of some time the pigment cells of the part affected are found to have congregated together round the minute vessels in a somewhat contracted condition, their long branching process becoming materially shortened. The contractility which these cells are known to possess, however, is not entirely abrogated. One or more of the processes may be seen to insinuate itself through the wall of the adjacent capillary. After penetration it may become much elongated, and be even altogether carried away by the current of blood, to the movements of which for a time it offers an impediment ; or it may, so to speak, drag after it the rest of the cell, which after remaining a little while adherent to the inner surface of the vessel at the point where it has entered, is swept, or itself swims away. Is not this a singular fact ? Of what nature must the capillary wall be, that will thus admit the ingress and egress of solid bodies, and yet retain the red blood corpuscles even under great increase of pressure.

M. E. LEFEVRE is engaged upon a monograph of the species of the genus *Clythra*, inhabiting Europe and its confines (including the Mediterranean region). As many new species have been discovered, especially in Algeria and the East, since the publication of Lacordaire's memoir in 1848, M. Lefèvre will be thankful for the loan of specimens of new or rare species, and for any information as to their geographical distribution. M. Lefèvre's address is 28, Rue Constantine, Paris-Plaisance.

WE quote the following from the *Scotsman*, of May 2:—"A correspondent writes: 'In Inverleith Row on Saturday night, exactly at a quarter-past eleven o'clock, my attention was attracted by a sudden and strange brightness overspreading everything around. Instinctively turning my eyes upwards, a grand sight met my gaze. A meteor of remarkable size, brilliancy, and distinctness, was seen shooting from the heavens, from about the zenith, and descending earthwards in a southerly direction. The form of this interesting object seemed elliptical, and it was of a bright yellow hue. It had a clearly-defined apex or point, which was of a deep red colour, and appeared to glow and sparkle in a wonderful manner. The phenomenon was visible for about two seconds, and lighted up everything around me. The night was fine and clear, with a decidedly frosty air, and there was a light, steady breeze blowing from the north-west at the time." On the same subject our Dunbar correspondent writes: 'A very brilliant meteor was observed here about eleven o'clock on Saturday night. When first seen, the meteor had the appearance of a star of the first magnitude. As it approached, however, it gradually increased in size until it assumed the appearance of a ball of five or six inches in diameter, and changing its colour from a pale silvery white to a bright blue flame. As it still increased, sparks seemed to be emitted from the circumference, giving it the appearance of being surrounded with a peculiar halo of dense silvery rays. It continued in this state for a second or two, and then shot across the heavens in a southerly direction, the ball increasing in brilliancy as it travelled, and leaving behind it a long train of lurid-coloured flame. From the time it was first seen approaching until it vanished about five or six seconds elapsed. The night was clear and cold at the time.'"

THE GRESHAM LECTURES

THE Lectures (three in number) were delivered by Dr. Symes Thompson, during the past week, at the Gresham College, Basinghall-street. The first was occupied with the consideration of Cough, an account being given of its etiology varieties, and general principles of treatment. The second was devoted to Tonics; whilst of the third, which treated of Climate and Health Resorts, we give an epitome as likely to prove interesting to some of our readers. Dr. Thompson remarked that the Romans very early discovered the use of mineral waters, as shown by many of their relics being found in the neighbourhood of such springs; whilst at Wiesbaden, tablets have been found with votive inscriptions. Some of the more common ingredients of mineral waters were then described, and their chemical properties demonstrated, including carbonic acid, iron, sulphuretted hydrogen, &c. The properties of ozone were then discussed in connection with pure air, and the lecturer passed on to the consideration of climate and health resorts, and said that it was a great mistake to suppose that any particular place was the best for a particular malady, for there is no specific action in the air of any place; and the physician, in recommending a resort to patients, had regard to the kind of climate there found, a dry climate being suitable for most bronchial membranes, and a moist climate for the reverse state of the membranes, and an approximation to such different climates can be obtained in our rooms. If the patient be feverish and excitable, he should be sent to an exciting varied climate; or, if languid and torpid, not to a quiet, mild, uniform climate. These two kinds of climate are obtainable at the south of France; for at Nice the climate is bright and exciting, while in the neighbourhood of the Pyrenees, at Pau, the atmosphere is very still, and eminently suitable to patients suffering from irritable membranes. The great advantage gained by persons going abroad is no doubt the regular daily outdoor exercise, not obtainable in the varied winter of our island, but found in Algiers, Riviera, Mentone, Nice, &c., at that season. Together with exercise may be linked the advantage derived from breathing pure air. There are, however, many places in England where almost the same benefit may be enjoyed. It was the former practice in cases of lung-disease, to shut up patients in close rooms, with fire burning, all through the winter, the consequence being that they became like hothouse plants, and on the first exposure to the open air in spring all these advantages were lost. Acting on the same principle, consumptive patients up to 20 years ago were sent to Madeira. Three years ago the inhabitants of Madeira, wishing to re-establish the value of their climate in lung-disease, solicited the authorities of the Brompton Hospital for Consumption to send them out patients as a matter of experiment. Twenty patients were sent out, and only those who were likely to be benefited by the climate of Madeira, being all in an advanced stage of lung-disease. Of this number 1 patient died suddenly, although up to the time of his death he seemed to be benefiting by the change; 4 were worse; 6 were stationary, and 7 were markedly benefited; 2 very much benefited. This has been regarded by some as unsuccessful; but Dr. Thompson was of different opinion, and thought it indicated that Madeira is a useful climate in certain cases. Since Madeira has been abandoned there has been a revulsion of feeling in favour of Canada as a resort for consumptives, but that this is no new doctrine is seen from the fact that the value of cold climates for consumption was advocated by Baron Larrey, Napoleon Bonaparte's physician. There are disadvantages as well as advantages in the most favoured health resorts; such as the dry, hot "mistral' of Nice, or the dry, dusty "brickfielder" of Melbourne,—winds which patients dislike as much as our east wind. Purity of air or absence of dust is of very great importance; and for this reason it is now the practice to send patients suffering from chest-disease for a long sea-voyage. It constantly happens that sick people—in whom the disease is far advanced—press their medical men to send them on a sea-voyage; but in their case the remedy has come too late, and so it happens that the death-rate at Melbourne is exceedingly high—more than half the deaths being due to consumption. Dampness favours consumption; so that dry air is another desideratum which can be obtained at certain altitudes—so that in certain districts it is found possible to resort to mountain-tops, where consumption does not occur. In the neighbourhood of the equator the so-called "immunity-level" is at a height of 9,000 feet; at Algiers, 6,000 feet; at London, 3,000 feet. The chief resorts in Europe are the Swiss mountains, where English people often go to spend the winter, in perpetual snow, but yet in an atmosphere so pure and clear that the most delicate invalids can go out in the open air. In Norway, Russia, &c., the immunity-level is only 1,000 feet above the sea.

SCIENTIFIC SERIALS

THE May number of the *Journal of Botany, British and Foreign*, commences with the first part of a *Clavis Agaricinorum* by the well-known fungologist, Mr. Worthington Smith. The general classification of the Agarics adopted by Fries and Berkeley is followed; but several new sub-genera are proposed. An ingenious tabular view accompanies the paper, presenting the salient features of the series and sub-genera of this vast genus at a glance. Dr. Seemann continues his revision of the natural order *Bignoniaceæ*; while the Hon. J. L. Warren contributes a paper on a sub-division of *Rubus*, a most intricate genus, to which he has paid special attention; and Dr. H. Trimen a description of a new British *Callitriche*. Other short notes and notices fill up the number, which maintains the interest for British botanists especially, promised on the commencement of the new series.

The *Revue des Cours Scientifiques* for April 23rd contains a report of an interesting address delivered before the University of Berlin, by M. du Bois Reymond on the Organisation of Universities; the conclusion of Fotherly's address to the Hunterian Society, and report of a lecture by M. Claude Bernard, on Suffocation by Charcoal. The number for April 30th is entirely occupied by M. Bouley's lecture at the Sorbonne, on Madness, and the conclusion of M. Bernard's lecture.

THE third number of the new Italian Geological Journal, or *Bolletino*, published by the "Comitato Geologico d'Italia," opens with M. Igino Cocchi's paper on the stratified rocks of the isle of Elba. It especially relates to the lower secondary, eocene, cretaceous, and post pliocene strata, and is illustrated with engravings. Among the bibliographical notices, Professor Omboni's work on the Geology of Italy, with eight maps, is well spoken of. The number also comprises translations of extracts from foreign memoirs.

THE *American Naturalist*, Vol. IV., No. 2, April 1870.—The April number of this Journal contains three exceedingly interesting articles, namely, a report on the Sea Otters of the north-west coast of America and Aleutian islands, by Captain C. M. Scammon; a paper on Parasitic Insects, from the able hand of Dr. A. S. Packard; and some notes on the Fresh-water Fish of New Jersey, by Dr. C. C. Abbott, which contains many valuable remarks. The last two papers are illustrated.—Dr. W. Wood contributes a popular article on Falconry.—The usual reviews and short miscellaneous notices complete the contents of the number.

SOCIETIES AND ACADEMIES

LONDON

Royal Society.—April 28.—"On the Organs of Vision in the Common Mole." By Robert James Lee.

"On an Aplanatic Searcher, and its Effects in improving High Power Definition in the Microscope." By G. W. Royston-Pigott, M.A., M.D.

The Aplanatic Searcher is intended to improve the penetration, amplify magnifying power, intensify definition, and raise the objective somewhat further from its dangerous proximity to the delicate covering-glass indispensable to the observation of objects under very high powers. The inquiry into the practicability of improving the performance of microscopic object-glasses of the very finest known quality was suggested by an accidental resolution in 1862 of the Podura markings into black beads. This led to a search for the cause of defective definition, if any existed. A variety of first-class objectives, from the $\frac{1}{16}$ to the $\frac{1}{4}$, failed to show the beading, although most carefully constructed by Messrs. Powell and Lealand. Experiments having been instituted on the nature of the errors, it was found that the instrument required a better distribution of power; instead of depending upon the deepest eyepieces and most powerful objectives hitherto constructed, that better effects could be produced by regulating a more gradual bending or refraction of the excentrical rays emanating from a brilliant microscopic origin of light. It then appeared that delusive images, which the writer has ventured to name *eidola**, exist in close proximity to the best focal point (where the least circle of confusion finds its focus).

I. That these images, possessing extraordinary characters, exist principally above or below the best focal point, according as the objective spherical aberration is positive or negative.

II. That test-images may be formed of a high order of delicacy and accurate portraiture in *miniature*, by employing an objective of twice the focal depth, or, rather, half the focal length, of the observing objective.

III. That such test-images (which may be obtained conveniently two thousand times less than a known original) are formed (under precautions) with a remarkable freedom from aberration, which appears to be reduced in the miniature to a *minimum*.

IV. The beauty or indistinctness with which they are displayed (especially on the immersion system) is a marvellous test of the correction of the observing objective, but an indifferent one of the image-forming objective used to produce the testing miniature.

These results enable the observer to compare the known with the unknown. By observing a variety of brilliant images of known objects, as gauze, lace, an ivory thermometer, and sparkles of mercury, all formed in the focus of the objective to be tested with the microscope properly adjusted so that the axes of the two objectives may be coincident, and their corrections suitably manipulated, it is practicable to compare known delusions with suspected phenomena.

It was then observed (by means of such appliances) that the aberration developed by high-power eyepieces and a lengthened tube followed a peculiar law.

A. A lengthened tube increased aberration faster than it gained power (roughly, the aberration varied as v^2, while the power varied as v).

B. As the image was formed by the objective at points nearer to it than the *standard distance of nine inches*, for which the best English glasses are corrected, the writer found the aberration diminished faster than the power was lost, by shortening the body of the instrument.

C. The aberration became negatively affected, and required a positive compensation.

D. Frequent consideration of the equations for aplanatism suggested the idea of searching the axis of the instrument for aplanatic foci, and that many such foci would probably be found to exist in proportion to the number of terms in the equations (involving curvatures and positions).

E. The law was then ascertained that power could be raised, and definition intensified, by positively correcting the searching lenses in proportion as they approached the objective, at the same time applying a similar correction to the observing objective.

The chief results hitherto obtained may be thus summarised. The writer measured the distance gained by the aplanatic searcher, whilst observing with a half-inch objective with a power of seven hundred diameters, and found it *two-tenths of an inch increase*; so that optical penetration was attainable with this high power through plate-glass nearly one quarter of an inch thick, whilst *visual* focal depth was proportionably increased. The aplanatic searcher increases the power of the microscope from two and a half to five times the usual power obtained with a third or C eye-piece of one inch focal length. The eighth thus acquires the power of a twenty-fifth, the penetration of a one-fourth. And at the same time the lowest possible eyepiece (3-inch focus) is substituted for the deep eye-piece formed of minute lenses, and guarded with a minutely perforated cap. The writer lately exhibited to Messrs. Powell and Lealand a brilliant definition, under a power of four thousand diameters, with their new "eighth immersion" lens, by means of the searcher and low eyepiece.

The traverse of the aplanatic searcher introduces remarkable chromatic corrections displayed in the unexpected colouring developed in microscopic test objects. The singular properties, or rather phenomena, shown by eidola, enable the practised observer in many cases to distinguish between true and delusive appearances, especially when aided by the aberrameter applied to the objective to display excentrical aberration by cutting off excentrical rays. Eidola are symmetrically placed on each side of the best focal point, as ascertained by the aberrameter when the compensations have attained a delicate balance of opposite corrections.

If the beading, for instance, of a test object exists in two contiguous parallel planes, the eidolon of one set is commingled with the true image of the other. But the upper or lower set may be separately displayed, either by depressing the false eidola of the lower stratum, or elevating the eidola of the upper. For when the eidola of two contiguous strata are intermingled, correct definition is impossible so long as the aperture of the objective remains considerable.

One other result accrues: when an objective, otherwise excellent, cannot be further corrected, the component glasses being already closely screwed up together, a further correction can be applied by means of the adjustments of the aplanatic searcher itself, all of which are essentially conjugate with the actions of the objective and the variable positions of its component lenses; so that if δx be the traversing movements of the objective lenses, δv that of the searcher, F the focal distance of the image from the objective when δx vanishes, f the focal distance of the virtual image formed by the facet lenses of the objective, then

$$\frac{\delta v}{\delta x} = \left(\frac{F}{f_1}\right)^2$$

The *appendix* refers to plates illustrating the mechanical arrangements for the discrimination of eidola and true images, and for traversing the lenses of the aplanatic searcher. The plates also show the course of the optical pencils, spurious disks of residuary aberration and imperfect definition, as well as some examples of "high-power resolution" of the Podura and Lepisma beading, as well as the amount of amplification

* From εἴδωλον, a false spectral image.

obtained by Camera Lucida outline drawings of a given scale.

"On a Cause of Error in Electroscopic Experiments." By Sir Charles Wheatstone, F.R.S.

To arrive at accurate conclusions from the indications of an electroscope or electrometer, it is necessary to be aware of all the sources of error which may occasion these indications to be misinterpreted. In the course of some experiments on electrical conduction and induction which I have recently resumed, I was frequently delayed by what at first appeared to be very puzzling results. Occasionally I found that I could not discharge the electrometer with my finger, or only to a certain degree, and that it was necessary, before commencing another experiment, to place myself in communication with a gas-pipe which entered the room. How I became charged I could not at that time explain; the following chain of observations and experiments, however, soon led me to the true solution. I was sitting at a table not far from the fireplace, with the electrometer (one of Peltier's construction) before me, and was engaged in experimenting with disks of various substances. To ensure that the one I had in hand, which was of tortoise-shell, should be perfectly dry, I rose and held it for a minute before the fire; returning and placing it on the plate of the electrometer, I was surprised to find that it had apparently acquired a strong charge, deflecting the index of the electrometer beyond 90°. I found that the same thing took place with every disk I thus presented to the fire, whether of metal or any other substance. My first impression was that the disk had been rendered electrical by heat, though it would have been extraordinary that, if so, such a result had not been observed before; but on placing it in contact with a vessel of boiling water, or heating it by a gas-lamp, no such effect was produced. I next conjectured that the phenomenon might arise from a difference in the electrical state of the air in the room and at the top of the chimney; and to put this to the proof, I adjourned to the adjacent room where there was no fire, and bringing my disk to the fireplace I obtained precisely the same result. That this conjecture, however, was not tenable was soon evident, because I was able to produce the same deviation of the needle of the electrometer by bringing my disk near any part of the wall of the room. This seemed to indicate that different parts of the room were in different electrical states; but this again was disproved by finding that when the positions of the electrometer and the place where the disk was supposed to be charged were interchanged, the charge of the electrometer was still always negative. The last resource was to assume that my body had become charged by walking across the carpeted room, though the effect was produced even by the most careful treading. This ultimately proved to be the case; for resuming my seat at the table and scraping my foot on the rug, I was able at will to move the index to its greatest extent.

Before I proceed further I may state that a gold-leaf electrometer shows the phenomena as readily. When I first observed these effects the weather was frosty; but they present themselves, as I have subsequently found, almost equally well in all states of the weather, provided the room be perfectly dry. I will now proceed to state the conditions which are necessary for the complete success of the experiments, and the absence of which has prevented them from being hitherto observed in the striking manner in which they have appeared to me. The most essential condition appears to be that the boot or shoe of the experimenter must have a thin sole and be perfectly dry; a surface polished by wear seems to augment the effect. By rubbing the sole of the boot against the carpet or rug, the electricities are separated, the carpet assumes the positive state and the sole the negative state; the former being a tolerable insulator, prevents the positive electricity from running away to the earth, while the sole of the foot, being a much better conductor, readily allows the charge of negative electricity to pass into the body. So effective is the excitation, that if three persons hold each other by the hands, and the first rubs the carpet with his foot while the third touches the plate of the electrometer with his finger, a strong charge is communicated to the instrument. Even approaching the electrometer by the hand or body, it becomes charged by induction at some distance.

A stronger effect is produced on the index of the instrument if, after rubbing the foot against the carpet, it be immediately raised from it. When the two are in contact, the electricities are in some degree coerced or dissimulated; but when they are separated, the whole of the negative electricity becomes free and expands itself in the body. A single stamp on the carpet followed by an immediate removal of the foot causes the index of the electrometer to advance several degrees, and by a reiteration of such stamps the index advances 30° or 40°. The opposite electrical states of the carpet and the sole of the boot were thus shown: after rubbing, I removed the boot from the carpet, and placed on the latter a proof-plate (*i.e.* a small disk of metal with an insulating handle), and then transferred it to the plate of the electrometer: strong positive electricity was manifested. Performing the same operation with the sole of the boot, a very small charge was carried, by reason of its ready escape into the body. The negative charge assumed by sole-leather when rubbed with animal hair was thus rendered evident. I placed on the plate of the electrometer a disk of sole-leather and brushed it lightly with a thick camel's-hair pencil; a negative charge was communicated to the electrometer, which charge was principally one of conduction, on account of the very imperfect insulating power of the leather. Various materials, as India-rubber, gutta-percha, &c., were substituted for the sole of the boot; metal plates were also tried; all communicated negative electricity to the body. Woollen stockings are a great impediment to the transmission of electricity from the boot; when these experiments were made I wore cotton ones. When I substituted for the electrometer a long wire galvanometer, such as is usually employed in physiological experiments, the needle was made to advance several degrees.

At the meeting of the British Association at Dublin in 1857, Professor Loomis, of New York, attracted great attention by his account of some remarkable electrical phenomena observed in certain houses in that city. It appears that in unusually cold and dry winters, in rooms provided with thick carpets and heated by stoves or hot-air apparatus to 70°, electrical phenomena of great intensity are sometimes produced. A lady walking along a carpeted floor drew a spark one quarter of an inch in length between two metal balls, one attached to a gas-pipe, the other touched by her hand; she also fired ether, ignited a gaslight, charged a Leyden jar, and repelled and attracted pith-balls similarly or dissimilarly electrified. Some of these statement were received with great incredulity at the time both here and abroad, but they have since been abundantly confirmed by the Professor himself and by others. (See Silliman's American Journal of Science, July 1858.)

My experiments show that these phenomena are exceptional only in degree. The striking effects observed by Professor Loomis were feeble unless the thermometer was below the freezing-point, and most energetic when near zero, the thermometer in the room standing at 70°. Those observed by myself succeed in almost any weather, when all the necessary conditions are fulfilled. Some of these conditions must frequently be present, and experimentalists cannot be too much on their guard against the occurrence of these abnormal effects. I think I have done a service to them, especially to those engaged in the delicate investigations of animal electricity, by drawing their attention to the subject.

Royal Institution, May 2. Annual meeting.—Sir Henry Holland, Bart, M.D., D.C.L., F.R.S., President, in the chair. The annual report of the Committee of Visitors for the year 1869 was read and adopted. The books and pamphlets presented in 1869 amounted to 255 volumes, making, with those purchased by the managers, a total of 388 volumes added to the library in the year, exclusive of periodicals. Forty-seven new members were elected in 1869. Sixty-three lectures and nineteen evening discourses were delivered during the year 1869. The following gentlemen were unanimously elected as officers for the ensuing year:—President: Sir Henry Holland, Bart., M.D., D.C.L., F.R.S. Treasurer: William Spottiswoode, M.A., F.R.S. Secretary: Henry Bence Jones, M.A., M.D., F.R.S.

Royal Geographical Society, April 25.—Sir R. I. Murchison, Bart., President, in the chair. The following new Fellows were elected:—Baron Osten Sacken, Secretary to the Imperial Geographical Society, St. Petersburg (Hon. Corresponding Member); Thomas M. Blackie; Lieutenant Evelyn Baring, R.A.; Colonel Shuckburgh Denniss; George B. Hudson; Lord Lawrence, G.C.B.; and John Fenton Taylor.

A paper was read, entitled "An Expedition to the Trans-Narym Country," by Baron Osten Sacken. This paper, which had been translated from the Russian by Mr. Delmar Morgan, contained a narrative of a journey, undertaken for the purpose of a reconnaissance survey, by General Poltoratsky, across the

Thian-Shan Mountains to the vicinity of Kashgar. This territory became part of the Russian dominions by the treaty of Pekin in 1860, by which the frontier line was fixed as extending from the east of Lake Issyk-Kul, along the southern spur of the Celestial Mountains, to the Khokand country; but the terrritory had never yet been visited by a European. Starting from Fort Vernoë, north of Lake Issyk-Kul, the party turned the western end of the lake, and then marched nearly due south. The country was very mountainous and picturesque, five distinct lines of elevation belonging to the Thian-Shan system being crossed in succession, some of them by passes upwards of 12,000 feet in height. The intervening valleys are traversed by streams, forming the head-waters of the Jaxartes, the largest of which is the Narym; and on the elevated ridges lie two beautiful alpine lakes, the Sou-Kul and the Chatir-Kul. Game is very abundant along the banks of the rivers, and the country is but thinly peopled by tribes of Kirghizes. The Russians did not gain possession of the new territory without a severe struggle with the forces of the neighbouring independent state of Khokand, who, in October 1860, marched an army of 40,000 men against the small Russian force, but were defeated. Baron Osten Sacken paid great attention to the botany of the country passed through, and noted the various zones of vegetation, from the wooded lower slopes of the Thian-Shan to the treeless plains below the snow-line. The alpine flora he described as extremely rich and beautiful in colour and form—amongst the plants he mentioned *Anemone narcissiflora*, Ranunculi, Geraniums, Potentillas, Gentians, and other genera—showing a great resemblance between the productions of the Thian-Shan and the Himalaya. The expedition reached to within two marches of Kashgar, and then returned to Fort Vernoë.

A second paper, on "Recent Russian Explorations in Turkistan," was read by Mr. Delmar Morgan. In the discussion which followed, M. Bartholomei, of the Russian Legation, spoke of the friendly rivalry which now prevailed between Russians and English in the exploration of Central Asia. Sir Henry Rawlinson enumerated three new expeditions to different parts of Turkistan, in which the Russians were now engaged, and the scientific results of which were freely communicated; and he congratulated the President, Sir Roderick Murchison, on the actual realisation of his anticipations of former years, when Russia and England would be friendly rivals in completing our acquaintance with the geography of the respective boundaries of each in their Eastern possessions.

Ethnological Society, April 26.—Prof. Huxley, F.R.S., in the chair.—Dr. Donovan read a paper on "The importance to the Ethnologist of a careful study of the Characters of the Brain."—Mr. E. B. Tylor then read a communication "On the Philosophy of Religion among the Lower Races of Mankind." Generalising from the lower religions of the world, the author stated the principle on which, in his view, was developed the philosophy of what may be called Natural Religion. Taking the doctrine of spiritual beings as the minimum definition of religion, he described it as *animism*, a term which fits with the theory put forward, that the conception of the soul as recognised by the lower races, is the starting-point of their religious philosophy. Such a soul, combining the ideas of ghost and vital principle, explains the phenomena of life, disease, dreams, visions, &c. This idea is extended to animals and inanimate objects, which are considered to have souls capable of appearing after death or destruction. On the analogy of the body and soul, the actions of nature are explained on the animistic theory as worked or controlled by soul-like spiritual beings. Of these beings an immense number are held to be actually human souls or manes. To such beings are ascribed the phenomena of disease, especially epilepsy and mania. Similar in nature, though different in function, are the spirits of trees, springs, &c. Hence the savage polytheist rises to expanded conceptions of greater deities, as Sun and Moon. At an early period he separates the cause of good from that of evil, and hence Dualism is rooted deeply in the religion of the lower races. The culminating conception of a Supreme Deity is well known to many of the lower races.—The President, Mr. Pusey, Mr. Howorth, and Dr. Hyde Clarke, joined in the discussion on this paper.

N.B.—It should have been stated in the report of the last meeting, that the paper "On the Danish Element in the Population of Cleveland" was written by the Rev. J. C. Atkinson, of Danby.

PARIS

Academy of Sciences, April 25.—M. Chasles presented a note by M. H. Durrande, on surfaces of the fourth order, and a communication from Mr. Spottiswoode concerning a theorem brought before the Academy on the 21st of March last, and of which he now gives the following enunciation:—"Every point of a surface is sextactic in ten of the sections made by the planes of a bundle of which the axis passes through the point." —M. de Saint Venant presented a memoir on the pressure of soils, containing a comparison of his estimates from the rational consideration of the limit of equilibrium, and by the employment of the so-called principle of least resistance of Moseley. —Several papers on subjects connected with physics were read. M. Becquerel communicated some experimental researches by MM. Lucas and Cazin, upon the duration of the electric spark. M. Jamin presented a note by M. A. Trève, on electric currents, containing some curious and interesting experiments on the action of currents in opposite directions, and when crossed in vacuum-tubes. A note by M. Rénou, on the latent heat of ice, deduced from the experiments of Laplace and Lavoisier, was communicated by M. C. Sainte-Claire Deville. The author referred to a note by M. Jamin, in which the correctness of the experiments made by Laplace and Lavoisier was maintained, and stated that the accordance of results obtained by M. Jamin could only be fortuitous, as the thermometers employed by the old experimenters were inaccurate.—M. H. Sainte-Claire Deville presented a note on the formation of liquid drops, by M. Duclaux. The author described experiments with distilled water, and with alcohols of different strengths, and stated that in the formation of drops phenomena of cohesion have but little action. Drops of water are formed much more rapidly in vapour of alcohol than in the air, and yet the amount of alcohol dissolved is very small, and hence the author concluded that the effect is produced only upon a very thin superficial layer of the drop, the tension of which constitutes the resisting power determining the size of the drop. He extended these considerations to the formation of emulsions, and to various liquids in the organism.—A paper on the fixed characteristic notes of the different vowels, by M. R. Kœnig, was presented by M. Regnault. The author discussed the results obtained by MM. Helmholtz and Donders, and gave the following as that of his own investigations into the musical notes of the vowels.

OU	O	A	E	I
(si♭)2	(si♭)3	(si♭)4	(si♭)5	(si♭)6

giving in round numbers of simple vibrations: 450, 900, 1,800, 3,600, 7,200.—Numerous papers relating to astronomical subjects were communicated, and M. Delaunay read a note on the discovery of a new telescopic planet at the Observatory of Marseilles on the 19th April. This is the 110th asteroid of the group between Mars and Jupiter, and M. Delaunay proposes for it the name of *Lydia*. Its position on the 19th April, at $10^h\ 33^m\ 13^s$, mean time at Marseilles, was as follows:—

$$A\ R = 12^h\ 2^m\ 39^s,\ 22.$$
$$D = +6°\ 50',\ 38''.\ 8$$

Horary movements { in right ascension — 1^s 77 / in declination + 2″. 20

Magnitude 12 — 13.

M. Faye presented three memoirs, namely: a report on the operations of M. Respighi in spectral observation of the solar protuberances; a note on the recent experiments of M. Wüllner on the spectra of hydrogen, oxygen, and nitrogen, with reference to those of the solar protuberances; and a note on the processes of photographic observation proposed by M. Paschen for the coming transit of Venus.—A letter from Father Secchi on the results of some spectral observations of the sun was also read.—M. Delaunay presented, on the part of M. Flammarion, a reply to the objections raised by M. G. Quesneville to his law of the rotatory movement of the planets.—M. Chapelas presented a note on a luminous meteor of great brilliancy observed at Paris on the night of the 19th of April. This meteor passed from near σ Herculis to the neighbourhood of $\delta\ \epsilon\ \zeta$ Cephei, describing a trajectory from S. to N. of 48°. Its colour was green, and it had a long train. Its disappearance was preceded by three noiseless explosions, accompanied by flashes which illuminated the hills round Paris. Its apparent size was 6 or 7 times that of Jupiter.—The subject of arctic explorations was treated by M. C. Grad, who suggested as an untried route for attempting to reach the North Pole, the passage through the Sea of Kara and the Siberian Ocean.—The chemical papers were the following: Researches upon new platinic derivatives of the phosphorus-bases, by MM. A. Cahours and H. Gall; on the utilisation of the secondary products obtained in the manufacture of chloral, for the preparation of the æthylamines on a large scale, by M. A. W. Hofmann; thermical investigations of iodic acid, by M. A. Ditte, communicated by M. H. Sainte-Claire Deville; and thermical investigations of the states of sulphur, by M. Berthelot, presented by M. Balard.—M. A. Béchamp communicated a memoir on geological "microzymas" of various origin, in which he described the action of different rocks in producing alteration and fermentation of starch-paste, and sugar. He maintained that in all limestones, from the Great Oolite to the most recent Tertiaries, there exist living organisms (for which he has proposed the name of *Microzymas*), of the nature of the molecular granules observed in certain fermentations, and that these are the agents which produce the changes described by him. He stated that pure carbonate of lime has no such action.—M. Milne-Edwards presented a note by M. Jourdain on the mode of action of chloroform, upon the irritability of the stamens of *Mahonia*. Exposure for from 1 to 3 minutes to the vapour of chloroform was said to destroy temporarily the irritability of the stamens; exposure for 10 minutes or a quarter of an hour kills the portion of the plant subjected to it.—A note on the primitive type of the mammalia, by M. A. Roujou was read.—M. C. Robin communicated a note by M. Girard-Teulon on the law of the rotations of the eye-ball in the associated movements of the eyes, in which the author supported the views of Donders, in opposition to those of Helmholtz and Listing, and indicated what, in his opinion, had led the latter writers to a false conclusion.—The Abbé Richard communicated an account of the discovery of a workshop for the manufacture of flint instruments in Palestine.—This workshop is near the village of El-Bire (the ancient Beëroth), about twelve kilometers from Jerusalem; the author found *haches*, scrapers, knives, and saws, the last said by him to be very remarkable.—Besides these, and two papers on medical and surgical subjects, several notes were read of which the titles only are given.

VIENNA

Imperial Academy of Sciences, Feb. 3.—Prof. P. Redtenbacher presented on the part of Prof. H. Will, "An investigation of white mustard seed." In place of the myronate of potash of black mustard seed, the white mustard contains *sinalbine*, decomposable into sugar, a sulphocyanic compound and an acid sulphate. The sulphocyanic compound contains the radical *akrinyle* $C^7 H^7 O$, and when freed from sulphur and treated as nitryle with alkali furnishes ammonia and the salt of an acid = $C^8 H^8 O^3$, which melts at 277° F., and is not identical with any known acid of the same formula. The acid sulphate contains sinapisine, and the author contrasts the products of black and white mustard as follows:—

	Myronate of Potash.		Sugar.		Mustard Oil.		Sulphate of Potash.
1.	$C^{10} H^{18} NS^2 KO^{10}$	=	$C^6 H^{12} O^6$	+	$C^4 H^5 NS$	+	$SO^4 K H$
	Sinalbine.		**Sugar.**		**Sulphocyanide of akrinyle.**		**Sulphate of sinapisine.**
2.	$C^{30} H^{44} N^2 S^2 O^{16}$	=	$C^6 H^{12} O^6$	+	$C^8 H^7 NOS$	+	$SO^4 (C^{16} H^{14} NO^5) H$

February 10.—Mr. Joseph Rauter forwarded a memoir on the "Developmental history of some of the hairy structures of plants belonging to various families of *Dicotyledons*." He noticed that in some cases the hairs are simple products of the epidermal cells; whilst in others, although the first rudiment of the hair takes its origin from an epidermal cell, at a later period the subjacent parenchyma and the neighbouring epidermal cells take part in its structure; and in others, again—such as the spines and glandular hairs of roses—the first rudiment of the structure springs from the subcuticular tissue. As examples of the first mode of development, he cites the woolly hairs of *Ribes*, *Rosa*, &c., the stellate hairs of *Hieracium pilosella*, and the glandular hairs of *Hieracium*, *Azalea*, &c.; of the second, the stings of the nettle, the clinging hairs of the hop, and some other forms.—Dr. Boué presented the first portion of his mineralogico-geognostic observations made during his travels in Turkey in Europe, and relating to North Albania, Bosnia, Hergezowina, and Turkish Croatia.—Prof. J. Redtenbacher communicated the results of an investigation of some Austrian hydraulic magnesian lime which had been made in his laboratory by M. P. G. Hauenschild. The material contained about sixty per cent. of carbonate of lime, and thirty per cent. of carbonate of magnesia; when burnt at about 752° F. it furnished an excellent hydraulic cement.—Prof. Hlasivetz made a preliminary communication "Upon a new acid from grape sugar." He referred to his discovery of lactonic acid by the treatment of sugar of milk with bromine, and indicated that the only difference between the two bodies consists in the presence of one more atom of oxygen in the acid. A similar acid was produced by treating other sugars with bromine, but the hydrobromic acid formed in the reaction prevented its separation. The author induced M. Habermann to treat grape sugar with chlorine instead of bromine, and he has obtained the expected acid, having the formula $C^6H^{12}O^7$.—Dr. S. L. Schenk communicated a memoir "On the distribution of gluten in the wheat-grain," and Prof. Lang some "Crystallographic-optical determinations" relating to thirteen substances, chiefly of organic origin.

Imperial Geological Institution, April 5.—Th. Fuchs on the fossil shells of the Congeria-beds from Radmanest, near Lugas (Banat). A comparatively large number of species (48, 32 of them hitherto unknown in Austria), but of small size, characterise this fauna, and correspond to the fauna of the so-called Upper Steppen-Kalk (limestone of Odessa) in southern Russia. The small amygdaloid *Congeria simplex*, recently described by Barbot de Marny, which alone forms whole beds of the Odessa-limestone, is also found abundantly in Radmanest. Among the small Cardiadæ of the Odessa-limestone, some species differ from the usual type of the genus by possessing a sinuated pallial line. Very interesting is therefore the discovery of a new species of *Congeria* at Radmanest, which differs in the same way from the generic type of Congeria.—Ch. v. Hauer on the coking of brown coal. A series of experiments with the brown coal from Fohnsdorf (Styria) gave very satisfactory results. Cokes were obtained with a heating power equal to that of the cokes of good black coal; the proportion of sulphur was essentially diminished, and the cokes are firm enough to support the pressure of a high furnace. V. Hauer thinks that, mixed with cokes of black coal, they would be applicable to the smelting of iron, a problem the solution of which would be of the utmost importance for the iron manufacturers in the Alpine iron districts.

April 23.—Ferd. Baron v. Andrian on the Volcanic Rocks of the Bosphorus. An accurate investigation of the geological relations, the mineralogical characters, and the chemical constitution of these rocks, which border the mouth of the Bosphorus to the Black Sea, served to distinguish a series of different varieties which in part are almost perfectly identical with the trachytic rocks of Hungary and Transylvania. In both countries generally three types may be distinguished, viz.: green andesites and dacites; black augit-andesites, and rhyalithes.—Prof. Ch. Zittel from Munich contributed some remarks on the tithonic strata. His important memoir on the fossils of the Stramberg limestone will be followed within a few weeks by another on the fossils of the cliff limestone (Klippenkalk) of the environs of Rogoznik and Csarsztyn (Galicia), and the tithonic cephalopod-limestone of Southern Tyrol and Italy. His studies have brought him to the conclusion that an exact line of demarcation does not exist between the Jurassic and the Cretaceous formation. Prof. Ch. Hoffmann of Pesth announced the discovery of Triassic fossils in the older Dolomite—and limestone-rocks of the environs of Ofen, which had formerly been thought to belong to the Rhaetic series. — M. Ch. Paul has examined the Lignite-beds of western Slavonia. In a thickness of more than 6 feet they are to be found along a line of 15 German miles in length, they belong to the upper Miocene formation (Congeria or fresh-water beds of the Vienna Basin), which contains many fossils, among them chiefly to be noticed a very large new species of Unio.—Dr. Em. Tietze, of Breslau, spoke about the fossils of the carboniferous limestone of Silesia. Nearly two hundred different species have been found therein, they will be described in a special memoir.—M. Fr. Posepny on the lead-mines of Raihl in Carinthia. The ores are imbedded in irregular masses in a stratified limestone of Triassic age. They form neither layers nor true veins, but are dependent on dislocations in the limestone-strata, and the over-lying schists.

BERLIN

German Chemical Society, March 28.—M. G. Krämer has investigated the products accompanying the formation of chloral from alcohol. Besides chloride of ethyl already recognised by Hofmann, both chloride of ethylene, and chloride of ethylidene, as also the monochlorinated substitution compound of both have been isolated. Chlorinated chloride of ethylene $C_2 H_3 Cl_3$ boils at 115° and yields with potash $C_2 H_2 Cl_2$ boiling at 37° and transforming itself into a solid polymeric modification.

Chloride of ethylidene and ammonia produce collidene. Professor Hofmann, in continuance of former researches, has transformed methylated and amylated sulpho-ureas into trimethylated and triamylated melamines by the action of oxide of mercury. This reaction however is but secondary, the first products being substituted (neutral) cyanamides, which by repeated evaporisation become suddenly transformed into alcaline melamides. The ethylic, and the phenylic sulpho-ureas behave in the same manner. The transformation consists in three molecules of cyanamide uniting into one of melamine—

$$3\,C\,H\,(C_2\,H_5)\,N = C_3\,H_3\,(C_2\,H_5)_3\,N_3$$

The same chemist, in conjunction with Dr. Olshausen, publishes researches on polymeric modifications of cyanetholine, and its homologues. These researches are connected with the foregoing paper by the following consideration. A certain analogy between ethylcyanamide $C\,N\,(C_2\,H_5)\,H\,N$ and cyanetholine—$C\,N\,(C_2\,H_5)\,O$ allows us to predict that the latter will treble, in the same way that the former does. This has been found to be the case. By passing chloride of cyanogen into methylate of sodium, the cyanetholine of the methylic series (an oil) forms at the same time, with crystals of the formula—

$$\left.\begin{matrix}(C\,N)_3\\(C\,H_3)_3\end{matrix}\right\}O_3$$

cyanurate of methyl. These crystals fuse at 134° but are transformed by distillation into the isomeric compound—

$$\left.\begin{matrix}(C\,O)_3\\(C\,H_3)_3\end{matrix}\right\}N_3$$

fusing at 175°. The former treated with potash yields cyanuric acid, and methylic alcohol; the latter carbonic acid and methylamine. The former, treated with ammonia, forms the dimethylic ether of amido-cyanuric acid—

$$C_3\,N_3\left\{\begin{matrix}C\,H_3\,O\\C\,H_3\,O\\H_2\,N\end{matrix}\right.$$

The same compound is formed (together with cyanurate of methyl) when chloride of cyanogen is passed into methylate of sodium, and may be separated from the cyanurate, by the action of ether, in which it is insoluble. The circumstance that the corresponding ethyl-compound dissolves in ether, renders the investigation of the transformation of cyanetholine more difficult. Analogous results have been obtained when chloride of cyanogen was passed into amylate and phenylate of sodium.

Professor Rammelsberg, in a paper on the phosphates of thallium, stated that isomorphism exists between

1. $H\,Tl_2\,PO_4\,H_2\,O$ and $H_2\,Na\,PO_4\,H_2\,O$
2. $H_2\,Tl\,PO_4$ and $H\,(NH_4)_2\,PO_4$
3. $H\,Tl_2\,PO_4$ and $H_2\,(NH_4)\,PO_4$

This he considers as the first proof of the isomorphism of hydrogen with monatomic metals. The same is stated of a phosphoborate of magnesium found in the saltlayers of Lüneburg, and analysed by Nöllner, who gives it the formula $Mg\,B_2\,O_4.\ 2\,H\,Mg\,PO_4$. De Koninck and Marquardt have investigated Bryonicine, one of the two bases contained in the roots of *Bryonia dioica*, and give it the formula $C_{10}\,H_7\,N\,O_2$. P. Marquardt described polybromides of tetraethyl ammonium. Dr. Coninck described modifications of Bunsen's sucking apparatus for filtering, and of Mitscherlich's potash bulbs for combustion. M. Ballo recommends the preparation of binitronaphthol by oxydising naphthylamin with nitric acid. By the action of monobrominated naphthalin on rosaniline, he has produced a violet colouring matter, not yet analysed. W. Doer has prepared azonaphthaline by heating nitronaphthaline with zinc powder. F. Rochleder has found four new colouring substances in madder, $C_{14}\,H_8\,O_4$ isalizarine; and its homologue, a very similar substance, $C_{15}\,H_{10},\,O_4$; a third called hydrisalizarin, $C_{28}\,H_{18}\,O_8$, and a fourth, homologous with the foregoing, $C_{29}\,H_{20}\,O_8$. The proportions in which these substances occur in madder are minute. N. Bunge on electrolysis communicates that nitrophenate of potassium yields to the anode nitrophenol and oxygen. Thiacetic acid and thiobenzoic acid yield bisulphide of acetyle, and bisulphide of benzoyl. But sulphocyanide of potassium, instead of yielding bisulphide of cyanogen, gives pseudo-sulphocyanogen. L. Henry has proved the identity of tribromhydrine of glycerine with the tribromide of allyle, from which it has hitherto been considered to differ. N. Lubarin, in submitting chloraluric acid to a renewed investigation, has arrived at the conclusion that it is impure parabanic acid mixed with chloride of ammonium. A. Ladenburg has found that, in support of Dr. Wanklyn's opinion, acetic ether perfectly free from water is not attacked by sodium below 100° C., and that in this reaction no evolution of gas takes place. For decomposing the water and alcohol generally contained in what is called pure acetic ether, the chlorides of silicium or of phosphorus were employed. Lastly, M. Vogel reported on Camuzet's experiments on gun-cotton, which differ so entirely from everything hitherto asserted, that they require confirmation. According to Camuzet, water dissolves the greater part of gun-cotton, separating at the same time the remaining part into a flocculent mass (the explosive ingredient of gun-cotton), and a granular non-explosive powder, which falls to the bottom of the vessel.

DIARY

THURSDAY, MAY 5

ROYAL SOCIETY, at 8.30.—On the Pre-Carboniferous Flora of North-Eastern America, and more especially on that of the Erian (Devonian) Period (Bakerian Lecture): Principal Dawson, F.R.S.

SOCIETY OF ANTIQUARIES, at 8.30.—On the Date of the Discovery of the American Continent, by John and Sebastian Cabot: R. H. Major, F.S.A.

LINNEAN SOCIETY, at 8. CHEMICAL SOCIETY, at 8.

ROYAL INSTITUTION, at 3.—Electricity: Prof. Tyndall.

FRIDAY, MAY 6.

ROYAL INSTITUTION, at 8.—Star-grouping; star-drift; star-mist: R. A. Proctor.

SATURDAY, MAY 7.

ROYAL INSTITUTION, at 3.—Comets: Prof. Grant.

MONDAY, MAY 9.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.

LONDON INSTITUTION, at 4.—Botany: Prof. Bentley.

TUESDAY, MAY 10.

ETHNOLOGICAL SOCIETY, at 8.30.—(Special meeting at the Museum of Practical Geology). Opening address: Prof. Huxley. On the Influence of the Norman Conquest in the Ethnology of Britain: Rev. Dr. Nicholas.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion on the Strength of Iron and Steel. Recent Improvements in Regenerative Hot Blast Stoves, for Blast Furnances: E. A. Cowper.

ROYAL INSTITUTION, at 3.—On the Principles of Moral and Political Philosophy: Prof. Blackie.

CONTENTS

ERRATUM.—By an error of the press, Prof. Duncan's Table of Madreporaria dredged up in the 'Porcupine' Expedition (No. 26, p. 663), was designated "Madreporaria of the Red Sea," instead of the "Deep Sea."

The INDEX and CONTENTS for Vol. I., will be published with an early number.

THURSDAY, MAY 12, 1870

A BUILDING FOR THE LEARNED SOCIETIES

THE Statistical Society has done good service to the cause of science in convening representatives of the learned societies, to consider whether it would not be possible to obtain a building for their accommodation worthy of the high position they occupy in this great metropolis. At this moment several societies are under notice to quit, others scarcely know where to look for shelter, and many more are utterly unable to find sufficient room for their libraries, instruments, and museums, though they pay a large portion of their income in rent and taxes. It is calculated that, jointly, upwards of 2,000*l.* a year is now paid in rent, enough, one would think, if properly managed, to supply most ample accommodation for very many societies, to say nothing of the great economy in service that would result from the joint occupation of a proper building. But so long as nothing is done to bring about some understanding and co-operation among the different societies, the evil is irremediable. Nor is it purely a question of finance. Many abstain from joining a learned society when its place of meeting is either inconveniently situated, or altogether too small for the usual attendance at the ordinary meetings. Not a few members of more than one society are unnecessarily driven from one place to another. The libraries for reference are not half utilised. Co-operation among men of science is almost impossible, and the action of each society is rendered thereby comparatively feeble and ineffective. On every ground, whether of convenience, economy, or utility, the learned societies would do well if they could combine in erecting a building sufficiently capacious for their joint accommodation.

Some learned societies have no reason to complain. The Royal Society, the Linnean, the Royal Astronomical, the Geological, the Chemical, the Society of Antiquaries, and a few others, are well accommodated, and a solid structure is being raised for them in Piccadilly. Those whose wants are yet to be supplied are the Statistical Society, the Institute of Actuaries, the Mathematical, Meteorological, Ethnological, Anthropological, Geographical, Archæological, and Juridical Societies, the Social Science Association, and as many more; and it is for them to consider whether it is better to go on as they are doing, paying one, two, or four hundred pounds a year each for their present rooms, or whether they would not do better by combining together for the erection of a proper building for them all. In calculating how many societies could unite for such a purpose, we must take into account the kindred character of their labour and inquiries. The statisticians, actuaries, and mathematicians might well meet together, and so it would be fitting that the antiquaries and archæologists should have a common habitation. But not so those that have nothing in common. Then the number of members and the space required for meetings, libraries, and museums are important elements. The Geographical Society, with its map-rooms and extensive library, would require space enough for a dozen other societies. And further, the frequency of meetings must be considered, when at the most only three or four commodious halls could be secured in any one building. We scarcely imagine, in fact, that any large number of societies could well be united in one building, and that will be a source of difficulty, especially in a financial aspect.

But why should there be any financial difficulty? Surely the erection of one or more buildings for purposes of science is a duty which may well rest with the Government. Nowhere does the State do so little for science as in this country. The estimates for 1870-71 give the entire sum to be applied to the learned societies at 2,370*l.*—a sum distributed among very few of them. Of this 500*l.* goes to the Royal Geographical Society, to provide suitable rooms in which to hold their meetings, and to exhibit to the public, free of charge, their collection of maps; 300*l.* is given to the Royal Society of Edinburgh; 500*l.* to the Royal Academy of Music; and 70*l.* to the Irish Academy of Music. In addition to this 160,000*l.* are appropriated to a building for certain learned societies in Burlington House; but it will serve for very few of them; and if we are rightly informed, the Government will reoccupy all the buildings in Somerset House now used by learned societies.

The chairman of the meeting at the Statistical Society stated that communications had passed between himself and the Chancellor of the Exchequer, and that no encouragement whatever was given for any application of this nature. But it is the clear duty of the societies not to rest satisfied with this, but to get a decided expression of opinion on the subject. By no means should the most natural and proper channel for obtaining the requisite sum for a building so essential to the well-being of the country be neglected.

But supposing the Government should turn a deaf ear to the application of the learned societies, are there no means available within these bodies themselves for getting the amount? It has been estimated that the probable cost of a building sufficiently commodious, though not ornamental, in some eligible locality near Charing-cross, will be, with the ground-rent, 30,000*l.* to 40,000*l.* Why should not a joint-stock company be formed for the purpose, and a large number of shares be taken up by the members of the societies interested? Some societies have moreover an accumulated fund of considerable importance. The Geographical Society has, it is understood, upwards of 20,000*l.* What more natural than to apply such investments in a palace of science, with an income so well guaranteed by the rental of the learned societies? The financial part of the question must be carefully but fearlessly approached. No insurmountable difficulties stand in the way of obtaining any reasonable amount for such a purpose.

What we want is a prompt and vigorous action on the part of the learned bodies. Heaven helps those who help themselves. The delegates at the meeting at the Statistical Society unanimously resolved in favour of co-operation on the subject, but by an unfortunate introduction of too cautious a spirit, they let the opportunity slip without naming a committee to prosecute the necessary inquiries and to digest a suitable scheme. Such a committee could not have committed the parties to any course of action. Its object would have been to place the proposal on a practical basis, so as to enable the societies to come to a right decision. As it is, the Conference decided to invite the societies—first, to confirm by their separate vote the joint resolve of their delegates, and then to give proof of their interest in the attainment of the object by nominating one or more members to act on a committee to be appointed for the purpose. The evil of such a course is, that much valuable time is lost in correspondence and negotiation before any practical step is taken in the matter. After all, however, the delay may be useful in ripening opinion on the subject. What is wanted in the steps eventually to be taken is energy of purpose and promptitude of action, for we are sure that the object in view will be eminently conducive to the welfare and progress of Science in the United Kingdom.

FOSSIL OYSTERS

Monographie du Genre Ostrea—Terrain Cretacé. Par Henri Coquand, Docteur és-Sciences, Professeur de Geologie et Mineralogie. (Paris: Baillière, 1869.)

OF the many able geologists whom France has produced, few have had better opportunities of observation, or have availed themselves of them to better purpose, than the author of this monograph. Distinguished alike by his skill and long experience as a palæontologist, and by his extensive knowledge of practical geology, M. Coquand has laboured long and well, and far and wide—not only in Provence, and Italy, and Germany, but in far distant regions in Spain and Africa, in valleys and mountains never before resounding to the blows of the geologist's hammer.

Those who are only acquainted with the chalk as it is seen exposed in quarries and cuttings on the green downs and wolds of England, can form but a very imperfect notion of its true character. As M. Coquand has shown in a paper lately read before the Geological Society of London,* the chalk of England, extensive as we are accustomed to regard it, is but a fragment when compared with that which is seen in the South of France. The utmost thickness of the English Cretaceous beds is found to be about 900 feet, while in Provence the same, or rather the equivalent beds are more than 4,000 feet thick. In England we are accustomed to arrange the chalk into three or four divisions, while in France their more extended development requires an entirely different arrangement, and thus we find no less than eleven different beds, the character and limits of which are now ascertained with great accuracy.

The French strata being thus so much more largely developed than the English, the character of the fauna is, as might be expected, infinitely more varied. The difference of nearly three thousand feet is principally represented in France by several marine and freshwater beds altogether unknown in England. In some places, as at La Cadière and Martigues, we find extensive beds of Hippurites and Radiolites—fossils almost unknown in England, lying ranged in close order as when they lived; and again, while we have been accustomed to regard the chalk as altogether of marine origin, we find in Provence a district of about 250 square miles, in which the upper chalk strata of England and the Charentes of France are represented by freshwater deposits 1,400 feet thick. These contain several hundred species of land and freshwater shells unknown elsewhere, associated with beds of lignite as compact as our own Newcastle coal, and like it worked extensively for fuel. Both from the palæontological and the geological evidence it would seem as if, at some time, while our Cretaceous deposits were interrupted and stationary, others of great magnitude, with a succession of faunæ essentially differing, as well from our own as from each other, were accumulating in the South of France, alternately depressed and elevated—sometimes a deep sea, sometimes a great lake, and not improbably at one time dry land.

* Quarterly Journal G. S., Aug. 1869, vol. 25, part 3.

After a careful study of the Cretaceous systems of many countries, M. Coquand, undeterred by the dread of taking charge of a family at once so numerous and so troublesome, has now been induced to prepare this monograph of all the Cretaceous oysters wherever found, to be followed by like monographs of the Tertiary, Jurassic, Triassic, and Permian formations. It is, we believe, the first, or at least the most important attempt to give a synopsis of any one genus occupying so extensive a range.

The results of M. Coquand's researches are sufficiently striking; he describes no less than 255 distinct species of chalk oysters (including Gryphæa and Exogyra), and of these he has given excellent figures in an atlas of 75 plates, in folio. As regards England, he has disclosed the poverty of the land as compared with our neighbours. Our chalk oyster beds have been examined as assiduously as the French, but they have been found much less prolific, While France possesses 115 well-marked species, England. according to Mr. Morris's catalogue, can show but 25, all of which, except one (*O. triangularis* of Woodward), seem to be found also in France.

Nor is the range of some species less remarkable than their abundance. Two of them (*vesiculosa*, and *ungulata* or *larva*) appear to be altogether cosmopolitan; the former being found alike in England, France, Algeria, Belgium, Spain, Poland, Russia, Sweden, North America, and Mexico; and the latter having been also traced through all these countries (except Poland and Mexico), and extending its range also to India.

But while some species are thus prone to wander, others are to be noted for their domestic habits. Out of 49 American species, five only have been met with in Europe; and of 27 in Russia, and 23 in Spain, no less than 10 in each of these countries are not found elsewhere.

It seems evident from our author's observations, that so far as these fossils are concerned the several zones of chalk which he has described are divided by "a hard and fast line," marking the limits of each as clearly as the Tertiaries are separable from the Secondary rocks. Of the several *Dordonien* species, not one is found in the *Campanien* beds, and of ninety-five found in the *Campanien* none are found in the lower beds, and the same observation applies to each of the seven or eight inferior deposits. Although it transcends all our powers of calculation to form even a conjecture, much less an approximate estimate of the ages of ages that should be allowed for the *creation* (or, if that word be not allowable, for the introduction or evolution) of these various forms, and the extinction of their predecessors, we may yet gather from these materials a somewhat better, although still utterly inadequate notion of the extreme deliberation, so to speak, exhibited in building up this portion of the earth's fabric.

M. Coquand's memoir can hardly fail to be welcomed as a valuable addition to our palæontological and geological literature, both for what it is, and for what it suggests. Monographs of the fossils of any one country can only be regarded as so many *Mémoires pour servir*—words and lines, rather than pages—of the geological record. Incomplete as that vast history must ever remain, it would be found far more available than it is if we could have a synopsis like the present of every important genus. Owing to their wide range, and the usually good state of preservation in which they are found, the study of these fossils cannot fail to be of value with reference to some questions of much present interest. As compared with the fauna of the Cretaceous seas, the fossil mammals of the Quaternary period, to which reference is so often made in these discussions, afford but very imperfect materials for testing the various theories which are from time to time put forward as to the succession of species. These Quaternary beds usually exhibit but broken fragments—*disjecta membra*, which, while lying on the surface, or tossed about in company with river or deluge gravels, have been subjected to so many chances and changes that the order of succession is often difficult, if not impossible, to ascertain; while, on the other hand, the fossils of the chalk, slowly accumulating during countless ages in the quiet depths of their seas, exhibit the exact order in which their multitudinous genera and species successively made their appearance and, having endured for their appointed seasons, finally disappeared.

If we could have monographs of other important families arranged upon a plan as comprehensive as M. Coquand's, how much less unsatisfactory might our speculations be upon the perplexed and perplexing questions of the origin, distribution, and extinction of species. When we consider the subjects of this memoir, their great variety and wide dispersion, although we might perhaps think it possible that, as we have heard, an oyster should be "crossed in love," we find it difficult to imagine the creature as existing under such conditions that one species, while engaged in "the struggle for existence," should starve out and extinguish another; or that any process of "natural selection" should avail to alter the formation of the hinge as well as the internal and external structure of the shell. Indeed, if any such change did occur, it must have been *per saltum*, since with these mollusks, numerous as they are, there are no forms that can fairly be recognised as transitional; for just as each zone or region of the chalk is marked by the presence of its peculiar fauna, so each species of this numerous family has a character of its own; it is *sui generis*, apparently without ancestors and without descendants. If, indeed, all the members of this great family, by virtue of some law or process of evolution, did descend from one common ancestor, we should expect to find their forms varied and numerous, instead of being, as to our sorrow we find them, more simple and far less numerous; so that instead of being permitted to choose from the two hundred and fifty-five kinds described by M. Coquand, we are reduced to the pitiful allowance of one poor "*native*," and from what we see and hear of *him* it seems not unlikely that he is to be the last of his race, and that ere long, Oysters, like Mastodons will be things of the past.

J. W. FLOWER

OUR BOOK SHELF

Mrs. Loudon's First Book of Botany, for Schools and Young Persons. New edition, revised and enlarged. By David Wooster. (London: Bell and Daldy, 1870.)

WE wish we could speak more favourably of this prettily got-up little book. Mrs. Loudon's writings did good service in cultivating a love of plants among the last generation; but when a new edition of an old manual is brought out, with the date of the current year on the title-page, and an editor's name as having "revised" it, we expect that it will be corrected by the light of the present state of scientific knowledge. In the present instance this has not been adequately done; of the inadequacy we may give but two instances. At p. 18 prickles are described as metamorphosed leaves, instead of, as they really are, indurated hairs, or processes of the epidermis. But a more serious erroneous description occurs in the case of the spores of ferns, which are said to differ from seeds "in not requiring to be fertilised by pollen" (do seeds require to be fertilised by pollen?) The reader is left to suppose that the young fern-plant springs direct from the spore, no reference whatever being made to the recent discoveries of the functions of the *pro-thallium*, *archegonia*, and *antheridia*. The arrangement is good, as also are some of the illustrations; but the book cannot be used as a manual by teachers or lecturers, without the errors being corrected from some other handbook.

A. W. B.

The Birds of Asia. By John Gould, F.R.S.

THE twenty-second part of this magnificent work has just been issued to the subscribers. It contains fifteen plates coloured by hand, including the great alced, four owls, two pheasants, three buntings, three piculets, Franklin's barbet, and the long-billed wren, accompanied by letter-press descriptions. Among so much that is beautiful and interesting, it is very difficult to particularise; but we cannot help referring to the charming little owlet dedicated to the late Sir Benjamin Brodie, the eminent surgeon, and named *Athene Brodiei*. Among the peculiarities of the bay owl found in Nepaul and the northern confines of India, Mr. Gould notices its friendship for wild animals, living on good terms with the tiger, and sometimes alighting on its back. We learn that one of the pheasants, the Chinese *Crossoptilon*, or Dallas's eared pheasant, is now domesticated in our Zoological Gardens; also that some eggs have been hatched there, and that female birds may be purchased for 15*l*. The long-billed wren (*Rimator malacoptilus*, Blyth), a small reddish-brown bird, with a droll apology for a tail, is said to be excessively rare, and one of the most curious and highly-interesting species in the Indian avi-fauna.

Zoologie et Palæontologie générales. Par Paul Gervais, Prof. d'Anatomie Comparée au Museum d'Histoire naturelle de Paris. Première Série. 4to. Planches 50. (Paris: Bertrand, 1867–69.)

THIS handsome volume, with its carefully executed plates, is, as the author states, an endeavour to make the treasures accumulated in the Museum of Natural History available for the advance of science. The present part is occupied with the consideration of various living and fossil vertebrated animals, and is introduced by a long account of the arguments, most of them familiar to our readers, respecting the duration of man's habitation of the earth, together with minute descriptions of bones of the animals found in various caverns in France. The second chapter treats of the Fossils of Armissan (Aude); the third of animals living at the present time in the French possessions in the North of Africa; the fourth of some fossil reptiles of the secondary period, especially including the archæopteryx; the fifth and last considers the different species of fossil reptiles.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The late Captain Brome

A SHORT time since I announced in your columns the decease of Captain Fred. Brome, late of Gibraltar, and well known to many of your geological readers for his great and successful labours in the exploration of the caves and fissures of the Rock. I then stated that Captain Brome had left a widow and eight children, wholly unprovided for; and this is literally the case. My object in this communication is to state that his numerous and warm friends in Gibraltar, and at Weedon where he died, have already commenced the collection of a fund for the relief and maintenance of his helpless widow and family, and to request that you will allow me space to say, that I shall be happy to receive and forward any contributions in aid of this fund.

Captain Brome was for twenty-two years Governor of the Military Prison at Gibraltar, from which post he was displaced towards the end of 1868. His removal to England last year with his large family necessarily involved him in considerable expense, incurred in the hope that his new appointment at Weedon might afford him a home and some prospect of providing for his children's education. These hopes, however, were destroyed in less than twelve months by the announcement that the prison at Weedon was to be disestablished. The anxiety lest he should thus be left without prospect of employment, and, as he feared, without any provision for the wants of his family, caused him such distress that, although a strong and energetic man and in the prime of life, he gradually sank, and died from mental depression on the 4th of March.

It is impossible to conceive a case more deserving of sympathy and support than that of his unhappy widow and children, or one more deserving of recognition by all lovers of science than that of Captain Brome, who had gratuitously devoted several years of his life, and the most unwearied personal labour, simply because he believed, and truly believed that he was promoting a scientific object.

Subscriptions will be received by me, and, I am kindly permitted to say, by Mr. W. S. Dallas, at the apartments of the Geological Society, Somerset House.

Relations of the State to Scientific Research.—II.

SCIENTIFIC men are of three kinds: the young, the middle aged, and the old. It is difficult to say which needs help the most; but there is one work in which they can all severally take part, and from which they can each obtain that comfortable leisure which is the one thing needful for original research. That work is simply the work of teaching. And here let me not be misunderstood. By teaching science, I do not mean the miserable practices now carried on, but teaching on a scale commensurate with the great needs of a great nation, and in a way calculated to bring about the blessings that follow inevitably on true, thorough scientific knowledge.

To illustrate my meaning, let me take a particular science, chemistry, as an example. Of the whole population of England there will certainly be a certain number of men whose minds are so set on chemistry that they would be willing to accept, while in the prime of life, with gladness the offer of posts which, while taking up about half their time in teaching chemistry, would enable them to devote the entire other half to original work, and yet bring up their families in decency and order. What the exact number of such men would be, I do not care to know; it probably would never be very great; it certainly would never exceed the demand for men to fill chairs of chemistry at properly organised laboratories established at various points all over the kingdom.

Now a livelihood may be gained, and even a fortune made, by teaching, but this can never be done by working half time. But such a man as we are picturing must work half-time only; and therefore the receipts from his actual teaching must be subsidised from elsewhere—the chair must be endowed by the Government, either local or imperial.

The occupant of such a chair would not be an idler. No idler would seek a post which would always entail a large amount of labour, and never would bring wealth. At the very worst, even if he did no original work, he would earn his salary by teaching. If he taught badly, that is a thing which can readily be recognised by competent persons, and he could be dismissed. The very desire of a man to take such a position would be of itself almost a guarantee that he would perform its duties properly, and bring forth the fruit expected of him. And calling to mind the well-known law of human nature that the more work a man has to do, the more he over-abounds in work, we may feel sure that the half life which teaching leaves to such a man will be filled with a whole life's exertion.

The work of such a man would lie almost exclusively in the way of systematic lectures and general superintendence of the laboratory. I need hardly say that that ought to be a small part only of the total teaching done in the place. There must be attached to the professor two, three, or more recognised assistants, who would be always in the laboratory, who would personally direct and nurse the students, who would carry on original work, partly on their own account and partly on behalf of their master, and who would receive a moderate fixed salary, sufficient to enable them to live without having to look to any other extraneous sources of income. Such men would of course be embryonic professors; and I know of no more pressing need than this, of finding livelihoods for young promising men in the interval between the studentship and the professorship. I weep when I think of how many admirable young men become outcasts to science for lack of these. It has been so with myself: full of zeal for science in my youth, and, what is more important, rich in the germs of large ideas, which I have since seen flourishing in other men's minds and bringing forth fruit of fame, I could find no resting place. I threw myself into practical money-getting life, with the hope that after a while my gains would provide me a comfortable afternoon of old age, in which I might return to my former love. I now have both time and money; but, alas! my mind has grown stiff in the ways of the world: the old ideas of my youth are now vain shadows which I cannot grasp. I find myself a wretched puddler, full of egotistic hobbies, productive of little oddities and trifling curiosities, but bringing forth nothing of real value or permanent worth. The young men make fun of me, and the chief men treat me with a courtesy which is at once patronizing and forced.

What is true of chemistry is, with minor differences, true of the other sciences. Under such a scheme as I have pictured, both young and middle-aged would be provided for. With a sufficient number of laboratories, some large and some small, some with eminent, some with useful men at their head, some with many, some with few assistants, it would come to pass that on the one hand the younger men would work under the beneficial influence of their chiefs, while on the other the men full of thoughts would find heads and hands near them to carry out their ideas. Is it not a crying shame that at the present time such a man as Huxley is completely isolated from the younger biological workers, and instead of, like Cuvier, having a large laboratory manned by an enthusiastic body of scholars, ready to dissect everything after its kind, is penned up in an abominable den in Jermyn Street, and distracted by the demands of triflers; has, in fact, to work upon the world through the bars of a prison cage? Is it not also a shame that one of the acknowledged foremost teachers of mathematics in Europe, in the focus of our national life, should feel himself compelled to forsake the work of teaching for a subordinate unscientific appointment in a University, when his right place would have been as instructor of the rising mathematicians of England?

But besides teaching, there is the task of examining the taught. And here again is a source of easy livelihood. I do not mean such kind of examinations as are carried on at present; that wretched system of papers, worked through at the rate of so many dozen a day and paid for at so much a hundred—work done by steam and ending in smoke. I mean a thorough system of *practical* examinations, carried on slowly and quietly, by a staff of professors and their assistants, and paid for in respect of the immense contingencies that hang upon the result and of the vast responsibilities of the examiners. I have not space to dwell on this; but it is a point which wants working out thoroughly and well. The task of examining ought to be one of the richest sources of income to a large number of scientific men, instead as now the odd pence of a few.

I maintain, then, that teaching and examining combined would support all the young and middle-aged scientific men in this country that have sound reasons for devoting themselves to a scientific life, and support them honourably and productively.

Touching the old, little need be said. Every man who has filled one of the above posts worthily while he had force to work ought to be pensioned when he gets old. The matter lies in a nutshell and needs no more words. But there will always be a few old men who for their eminence and their services would require special provision, and that not so much on their own account as for the sake of the younger men of their time. There ought to be some *rewards* for a scientific life, but they should be few and very carefully allotted. At all times, moreover, there will be a few, a very few men whose genius ought to receive plenteous and present recognition. Such men with the older distinguished men might form a small consulting body whose services in the way of advice would be at the command of Government, and the members of which would draw salaries on a scale feebly imitative of those of other Government officials. I believe the legal advisers of Government are pretty well paid, and yet scientific advice is altogether unrewarded. Such men would be then at liberty to work out their ideas; the best means being, of course, taken to choose those men only into whose soul the iron of science has entered, men whom it is impossible to keep from work.

Two more remarks and I have done. It may be objected that this scheme would make scientific success in large measure dependent on the power of teaching, and that original work would thereby go to the wall. I reply that that is altogether a fallacy, and if I had time I could show it.

Lastly, the question of expense of apparatus and other means of inquiry is altogether a secondary one. Government ought of course largely to provide these; but there would be no difficulty in distributing them on a plan similar to that of the grant to the Royal Society. It is the question of "scientific careers" that is the pressing one, and the one most difficult to settle.

Tails of Comets

In NATURE of 16th December, Prof. Tait advances the opinion that the tail of a comet consists of nothing but meteorites; mentioning in proof of this that the orbits of the August and November meteors have been determined, and found to be identical with those of two known comets. I do not question the importance of this most remarkable fact, but I think the older opinion, that the tail of a comet is gaseous, is demonstrably true. Sir John Herschel, in his "Elements of Astronomy," remarks with wonder how the tail, in the comet's perihelion passage, is *whisked round* in apparent defiance of the law of inertia, so as always to keep pointing away from the sun. Were the comet an assemblage of meteorites this would be impossible; the tail would, in that case, always lie parallel to the direction of the comet's orbit. The fact just mentioned as to the perihelion motion of the tail is, to my mind, a conclusive proof that the tail is not formed once for all, but is a cloud which is constantly in process of formation, and as constantly evaporated. This view is supported by the fact that Halley's Comet was seen to increase in apparent magnitude as it receded from the sun, in consequence, as was suggested, of the conversion of invisible vapour into visible cloud as the heat grew less intense.

Dr. Tyndall's suggestion, that the tail may be a cloud produced by actinic precipitation from an invisible atmosphere is, to my mind, the only plausible suggestion yet made on the subject.

Left-Handedness

IN reference to the letters which lately appeared in your periodical on "Right and Left-handedness," I beg to draw your attention to some remarks of Professor Hyrtl, the celebrated anatomist of Vienna, which were published several years ago, and the substance of which I now quote from the 4th edition of his "Handbuch der topographischen Anatomie," 2 vol. 1860.

"It happens in the proportion of about two in a hundred cases that the left subclavian artery has its origin *before* the right, and in these cases left-handedness exists, as it also often actually does in the case of complete transposition of the internal organs (Professor Hyrtl describes two cases), and it is found that the proportion of left-handed to right-handed persons is also about 2 to 100. Professor Hyrtl thinks that ordinarily the blood is sent into the right subclavian under a greater pressure than into the left, on account of the relative position of these vessels, that in consequence of the greater supply of blood the muscles are better nourished and stronger, and that therefore the right extremity is more used. In cases of anomalous origin of the left subclavian, &c., the reverse occurs, and therefore the left hand is employed in preference.

Kensington, May 3 ADOLF BERNHARD MEYER

Strange Noises heard at Sea off Grey Town

IN submitting the following to the notice of your readers, I am guided only by the desire of seeking a solution of what to me and to many others appears a very curious phenomenon. The facts related can be vouched for by numbers of the officers and crews of any of the R. M. Company's ships.

I must premise that this phenomenon only takes place with iron vessels, and then only when at anchor off the port of Grey Town. At least, I have never heard of its occurring elsewhere, and I have made many inquiries.

Grey Town is a small place, containing but few inhabitants, situated at the mouth of the river St. Juan, which separates Nicaragua from Costa Rica, and empties itself into the Atlantic, lat. 10° 54′ N., and long. 83° 41′ W. In this town there are no belfries or factories of any kind.

Owing to a shallow bar, vessels cannot enter the harbour or river, and are therefore obliged to anchor in from seven to eight fathoms of water, about two miles from the beach, the bottom consisting of a heavy dark sand and mud containing much vegetable matter brought down by the river. Now, while at anchor in this situation, we hear, commencing with a marvellous punctuality at about midnight, a peculiar metallic vibratory sound, of sufficient loudness to awaken a great majority of the ship's crew, however tired they may be after a hard day's work. This sound continues for about two hours with but one or two very short intervals. It was first noticed some few years ago in the iron-built vessels *Wye, Tyne, Eider*, and *Danube*. It has never been heard on board the coppered-wooden vessels *Trent, Thames, Tamar*, or *Solent*. These were steamers formerly employed on the branch of the Company's Intercolonial service, and when any of their officers or crew told of the wonderful music heard on board at Grey Town, it was generally treated as "a yarn" or hoax. Well, for the last two years the company's large Transatlantic ships have called at Grey Town, and remained there on such occasions for from five to six days. We have thus all had ample opportunity of hearing for ourselves. When first heard by the negro sailors they were more frightened than astonished, and they at once gave way to superstitious fears of ghosts and Obeihism. By English sailors it was considered to be caused by the trumpet fish, or what they called such (certainly not the *Centriscus scolopax*, which does not even exist here). They invented a fish to account for it. But if caused by any kind of fish, why only at one place, and why only at certain hours of the night? Everything on board is as still from two to four, as from twelve to two o'clock, yet the sound is heard between twelve and two, but not between two and four. The ship is undoubtedly one of the principal instruments in its production. She is in fact for the time being converted into a great musical sounding board.

It is by no means easy to describe this sound, and each listener gives a somewhat different account of it.

It is musical, metallic, with a certain cadence, and a one-two-three time tendency of beat. It is heard most distinctly over open hatchways, over the engine-room, through the coal-shoots, and close round the outside of the ship. It cannot be fixed at any one place, always appearing to recede from the observer. On applying the ear to the side of an open bunker, one fancies that it is proceeding from the very bottom of the hold.

Very different were the comparisons made by the different listeners. The blowing of a conch shell by fishermen at a distance, a shell held to the ear, an æolian harp, the whirr or buzzing sound of wheel machinery in rapid motion, the vibration of a large bell when the first and louder part of the sound has ceased, the echo of chimes in the belfry, the ricocheting of a stone on ice, the wind blowing over telegraph wires, have all been assigned as bearing a more or less close resemblance; it is louder on the second than the first, and reaches its acme on the third night; calm weather and smooth water favour its development. The rippling of the water alongside and the breaking of the surf on the shore are heard quite distinct from it.

What is, then, this nocturnal music? Is it the result of a molecular change or vibration in the iron acted on by some galvanic agent peculiar to Grey Town? for bear in mind that it is heard nowhere else, not at Colon, some 250 miles distant on the same coast, not at Porto Bello, Carthagena, or St. Marta. The inhabitants on shore know nothing of it. If any of your numerous readers can assign a likely cause, will they be pleased to state by what means, if any, its accuracy may be tested? If required, I can forward a specimen of the mud and sand taken from the anchor.

CHARLES DENNEHY, M.R.C.S.I., R.M.S. *Shannon*

[Our correspondent should dredge.—ED.]

The Newly-Discovered Sources of the Nile

RELUCTANT as I am to meddle with geographical discoveries made by the 'high *priori* road,' I cannot refrain from protesting against erroneous statements, which, if left uncontradicted, may acquire currency. The zealous geographer of former times sought for truth and accuracy. Treasuring truth, his knowledge increased with his information. But fashions are now changed. It has been found that one who starts in ignorance may every day alight on some novelty and wonder; and that since anything may be proved by data made for the purpose, the best mode of treating preceding information is to corrupt, change, and distort it as the case may require, so that instead of fettering invention, it may serve as proof of endless new discoveries. Captains Burton and Speke examined the northern end of what they called Lake Tanganyika. They saw it narrowing to a point and enclosed by hills, called by the latter officer the Mountains of the Moon. Six rivers, they learned, flowed into it from those hills. They did not examine nor approach the southern end of the lake; they differed in their accounts of it; and Captain Burton, in writing that it was often circumnavigated by the Arabs, made a statement repugnant to common sense. The pedlar Arabs cross the lake in ill-built boats, with savage crews, navigating only in daylight. They navigate it no more than is absolutely necessary for their trade with the interior, and not for pleasure or scientific purposes. Captain Speke measured the altitude of the lake, and on his second journey, going to a great extent over the same ground, he saw no reason to be dissatisfied with his previous hypsometrical observations. The result of his observation at Gondokoro was thought to prove the accuracy of his instruments. Yet the account given of the northern end of the lake is now rejected, while that of the southern end is obstinately adhered to; and as to the elevation of the lake, the *à priori* geographers find it convenient to add 1,000 feet to that assigned by Captain Speke.

Among the geographers of the new school, no one holds a higher rank than Dr. Beke. In devoting his labours to the mystery of the Nile, he very properly began at the base. He first adjusted the Mountains of the Moon and their everlasting snows. A warm admirer of Ptolemy, he nevertheless found it expedient to correct a mistake of the old Grecian, who thought that those mountains extended from W. to E. in lat. 12° 30′ S., whereas Dr. Beke discovered that they actually lie in a meridional line across the equator, and not far from the eastern coast. With the boldness of genius he set this chain of mountains, on the alleged authority of the East African missionaries, in a region where these missionaries emphatically declare that there is nothing of the kind. But having removed the Mountains of the Moon from the famed Land of the Moon, he now unaccountably removes the sources of the Nile as far as possible from the mountains supposed to give birth to them. He places them 1,000 miles S.W. of those mountains, on the eastern frontier of Benguela; and this he does, forsooth, because Dr. Livingstone announces the discovery of the real Lakes of the Nile (a batch of 20), just where Ptolemy set them, between lat. 10° and 12° S. Had Dr. Livingstone an opportunity of looking at Ptolemy's map he would have therein seen only two lakes, nine degrees asunder, and respectively in lats. 6° and 7°. But with time to study and understand his author, he would also have perceived that the positions thus indicated in false graduation are really close to the equator, respectively in 11′ N. and 39′ S. In Dr. Livingstone such a mistake is not surprising; in Dr. Beke it is inexcusable. But the latter, being inspired with a new hypothetical discovery, eagerly seizes on anything that will help him to develope it. The river Casabi he deems the chief, as being also the most remote source of the Nile. Its course eastward he concludes on the authority of Ladislaus Magyar, whose scientific attainments and reliability he, of course, rates highly. But the career of the Hungarian proves only his leaning to savage life. From the Brazilian navy Ladislaus passed into the service of the King of Calibar; and thence again he made his way to the interior of Benguela, where, marrying the daughter of a chief, he found himself in a short time the leader of a band of expert hunters. In 1850 he started, with his wife and 280 armed followers, on an excursion to the interior. The province of Kiboque, in which are the sources of the great river Casabi, was soon reached. Its forests, he says, extend far and wide, in lat. 6°S. But as the province in question reaches little north of the 12th parallel, it is evident that the Hungarian's science deserted him at first starting. He continued his march through Bunda, south of the river Lungobungo, in lat. 10° 6′ (13° would be nearer the truth), and at length after a 33 days' march, crossing the Liambegi, he arrived at Ya Quilem, in Kilunda. Now, the Portuguese traveller, Graça, travelling from Bihé in a parallel route, arrived in 33 days at Catende, 100 miles west of the Liambegi, so that we cannot doubt that Ya Quilem was not far east of that river, and not to the north, but probably much to the south of the 11th parallel. Yet Ladislaus places it in 4° 41′ S.! Such is the science on which Dr. Beke relies. When the latter says that in lat. 6° 30′ Ladislaus learned the eastward course of the Casabi, he totally misrepresents the facts. The Hungarian was much further south when he embraced the belief that the great river runs to Nyanza and Lake Mofo (near the Cazembe), that is, that it occupies the valley of the Luapula. Graça, who followed the river down a long way to the north, states his opinion (entirely mistaken by Mr. Keith Johnston), that the Casabi and Lulua are the head-waters of the Rios de Sena (the Zambeze). To these two foolish attempts at a great discovery must be added a third. Dr. Livingstone proclaimed that the Luapula flows into the Liambegi, and deforming their names, he reckoned among its tributaries rivers which run into the Lulua. If the concurrent and invariable testimony of three centuries can make anything certain, it is certain that the Casabi falls into the river of Congo, commonly called the Zaire. From the first visit of the Portuguese to Congo to the present day, the natives, when interrogated respecting the origin of their great river, have always answered that it comes from the Lake (Lobale) a-Kilunda (of Kilunda). This is properly the name of the country about the head-waters of the Liambegi, but the Portuguese, copied by Dr. Livingstone, apply it much more widely. The Casabi certainly does not rise in Kilunda, but it receives many streams from it, and unites with the Lulua, which is swelled by many more. The chief river of Kilunda is, we believe, the Lualaba, which turns westward to join the Lulua, while 8 or 10 days' journey further east the Luviri, a smaller, but still an important river, flows north-eastward to the Luapula. Between them, in about the meridian of 25° E., is a well-marked water-parting. The Lualaba is bordered by extensive salt marshes. One of its affluents—the Luigila—is said to flow over a bed of rock-salt. Hence, the Lulua or Lolo, which collects these waters, is, as its name implies, a salt river, and remarkable for its excellent fish. Lake Dilolo (the cerebral *d* here takes the place of *r*), has, for the same reason, an equal reputation. Fish, salt, and copper are the products which chiefly support the trade of the African interior, and the great emporium of this trade is Katanga, on the River Luviri. I now turn to Mr. Keith Johnston, who rejects, but not on the best grounds, Dr. Beke's hypothesis that the Casabi is the source of the Nile, and at the same time proposes another equally objectionable, namely, that the Chambezi, that is, the Luapula, flows round by the north and west into the river of Congo. Surely such extravagant conjectures would never be brought forward if, in the quarters that exercise an influence on geography, fair play were allowed to the information and common sense of all parties. An ignorant and overbearing patronage has the power of spreading darkness around. Mr. K. Johnston unfortunately fixed his attention on a sentence of Dr. Livingstone's letter, which is fitted only to mislead—a sentence, the dangerous indistinctness of which was pointed out by me in an early number of this paper (NATURE No. 3). Dr. L. plainly says that the Luapula flows down north past the town of the Cazembe, and 12 *miles below it*, enters lake Moero. The traveller here states not what he saw, for the Luapula is some miles west of the Cazembe's town, but what he misconceived. He may have meant that twelve miles from the town, towards the S.W., the river issues from the lake. It is easy to show that Lake Moero (a name made for convenience by strangers, but not used by the natives) lies to the S.W. of the Cazembe. Dr. L., when he first visited the Cazembe, passed (northwards) up the east side of the lake. He tells the difficulties created by the flooded rivers at its north end; one of these was the Luo, mentioned, as I have elsewhere pointed out, by the Portuguese as five days' distant from the Cazembe. Again, further north Dr. L. had to wade through the Chungu near an old site of the chief's town and where Larcerda died. Now, Father Pinto, when he left the Cazembe on his way homewards, did not reach the Chungu where he disinterred Lacerda's bones (subsequently lost in the retreat), till the 3rd day. Thus it is quite evident that the north end of Lake Moero is south of the Cazembe's residence. With respect to the course of the Luapula northwards, Mr. K. Johnston may rest assured that Dr. L.'s statements have not the slightest foundation. The Luapula does not take the name of Lualaba, nor does it join the Luviri towards the north. That the Chambezi falls into the Luapula was ascertained by Dr. Lacerda 70 years ago, and all that Dr. Livingstone has ascertained is that his own views on the subject were erroneous. As to the further course of these rivers let us take the evidently unbiassed evidence of the Arabs who met Dr. Livingstone in the interior of Africa, and a brief account of whose travels appeared in the transactions of the Geographical Society of Bombay, 1862. From the western shore they travelled in 27 days to the broad river Maroongo. This is the Luapula, which, by strangers reaching it from the north, is named after the Arungo, who dwell on its western side. "Roonda (Lunda) is on the banks of the Rooapoora, which runs north to Tanganyika." Here the rude observers confound the river which does reach the Nyanza, with Lake Mofo. Neither need we believe that the place is called Lunda by the natives. But this among African traders is a wide-spread name. By the Portuguese and their native agents the dominions of the Muata-ya-Nvo and of the Cazembe are all called Lunda. "25 days west (SW) of the Cazembe are the copper mines and the town Katanga. The river Rafira (Luviri) flows past Katanga, and joins the Rooapoora to the N." There is much reason for believing that the Luviri flows south-eastwards from Kanyika, but perhaps the author's meaning is that the river wheels round to the north. Dr. Livingstone saw nothing of Lake Bangweolo. Lake Moero he saw only on the east and north, and not connectedly; most of his statements respecting its size, &c., must be due to hearsay. The mountains that he speaks of are the hills Chimpire, noted in two groups by the Portuguese. It is remarkable that when in his missionary travels he met with the name Mpire, a hill, he supposed it to be the Sichuana numeral mbili, *two* (hills), a flagrant mistake. The Portuguese reported that the elevated country on the way to the Cazembe lies in ridges, with pools of water in the successive hollows. They learned that there was a great marsh at the confluence of the Chambeze and Luapula. Further north they saw numerous swamps and lagoons, and heard of more. They were told that to the west lay the great lagoon which Caetano Pereira spent a whole day in wading through. This was Carucuize, the nucleus of the Moero. The pombeiros, or native commercial travellers from Angola to the Cazembe, marched down the eastern bank of the Luapula five days before they turned eastward to Lake Mofo. That river, therefore, does not ordinarily flow through a lake. Dr. Livingstone evidently found the country in a state of unusual flood, with the fens and lagoons united into great lakes. From the district of the Fumo Moiro, at the north-east margin of the flood, he has made the name of the lake. As he finds every pool to belong to the system of the Nile, it is natural that, in his exalted imagination, the hills should rise into mountains. The Alunda, or Balunda as he calls them, being originally from the banks of the Lualaba, nourish a superstitious regard for that river. While the traveller, therefore, thought of nothing but the Nile, his native hearers knew of no great rivers but the Lualaba and its immediate neighbours, the Luviri and Luburi (in the printed letter misread Soburi.) His inquiries pointed to the N. or N.E.; they answered respecting the S.W. They mistook the object of his ardent curiosity, and he was only too ready to misinterpret their communicativeness. Hence the confusion of rivers, right and left, the lakes Ulenge, Chowambe, &c., of which the less said at present the better. After such a conclusion it may perhaps be consolatory to remark that it would be labour thown away to lead all the great rivers of south tropical Africa to the river of Gondokoro. Dr. Peney, who studied the character of this stream, found that it varied often, but that it never rose in flood more than two feet above its mean level. This increase in a wide spreading river near the equator barely suffices to compensate the loss by evaporation. Consequently, the floods at Gondokoro have no perceptible effect on the river a few degrees lower down. The river of Gondokoro, therefore, contributing nothing whatever to the floods of Egypt, must be regarded as a very subordinate branch of the Nile.

Dr. Beke wonders (NATURE, No. 9) why I give the name Nyanza to Lake Tanganyika. He here touches upon an important subject, interesting in its bearing both on geography and on the intrigues of geographical coteries. The assertion that in the name Lake Tanganyika there lurks some fraudulence, will of course be received with incredulity, and therefore its justification will be impossible without some historical development. But if encouraged, I am prepared to show that, with respect to the lake, the geographical world labours under a delusion designedly produced.

Apparent Size of the Moon

MY original intention was to put together several *veræ causæ*, which might be found, concurrently, to contribute to the universal impression that the moon's disc is larger or smaller, according as it is nearer to the horizon, or to the meridian. I shall content myself, however, with calling attention to what I am now persuaded is the nature of that impression. "Sweet are the uses of adversity." An attack of hemiopsia is always serious, and may be dangerous (see NATURE, Feb. 24th, 1870; p. 444). I think I owe to it the discovery (for such it was to me), that the variable standard of angular magnitude which infects our visual judgment, can be detected in a small room as certainly as in view of the celestial vault. The distressing affection which succeeds the hemiopsia, as soon as it forms a broken arch around the central hole of the retina, is an instructive spectre in regard to the question I am considering. Being referred to two equally distant sites on the wall of the room, one horizontal and the other considerably elevated, the spectre seems larger in the former than in the latter. I soon proved that this was no accident case. I extemporised a very rough experiment on this wise—I placed a disc $14\frac{1}{4}$ inches in diameter on the wall 7 feet from the ground, and selected a horizon so that the base of the disc and the horizon were equidistant from a fixed point of observation. I found the disc was about 30° above the horizon. I now took six persons successively, and made each person take an observation from that point, first looking at the disc, and then transferring it in mind to the horizon, where I carefully marked the estimated size. The maximum was $13\frac{5}{8}$, the minimum $10\frac{5}{8}$, and the mean $12\frac{1}{2}$ inches. This result is, of course, equivalent to saying that had an equal-sized disc been placed on the horizon, its diameter would, taking the average, have appeared to be $1\frac{3}{4}$ inch greater than when elevated 30° above it. I think it is worth while making this experiment with greater accuracy, and with a greater number of persons. I have no doubt Mr. Abbott's view of the case would be fully borne out. But I do not understand why the augmentation on the horizon is so much greater in the case of the moon and the sun; nor yet why the rising sun does not present so striking an augmentation as the rising moon. The augmentation of the latter may be partly an effect of external conditions; but the *fact* of augmentation, in what I have called visual judgment, is a question for the physiologist. I should much like to know what, for instance, such an authority as Helmholtz has to say on the matter.

The great fault of physicists, *me judice*, is, and ever was, their inability to see more than one side or aspect of a subject. Metaphysicians, on the contrary, may see all round it, but do not see all sides clearly. Mr. R. A. Proctor (NATURE, March 3rd, 1870; p. 462) affords me an apt example of the former. "The mind," he says, "instinctively assigns to the celestial vault a somewhat flattened figure, the part overhead seeming nearest to us." That is, taking the angular measure of the moon's diameter as a constant quantity, since she seems larger on the horizon than on the meridian, we must (unconsciously) refer her in the former case to a maximum distance. So far so good. But the argument is a thesis admitting of an equally valid antithesis. The case with me is this, that the moon appears to me to be much nearer on the horizon than in any other position! Nor am I singular in this. A lady proposed to me as an explanation of the apparently augmented size of the horizontal moon, that "probably she is nearer to us there than anywhere else!" Here we have the antithesis. We may say, the mind instinctively assigns to the celestial vault a somewhat prolate figure, the part overhead being furthest from us. That is, assuming (erroneously of course) a greater size for the moon's disc on or near the horizon (though she is not visually larger in one place than another), therefore we must infer that she is approaching us when she nears the horizon, thus showing us her size looming larger as she gets nearer. The arguments cut each other's throats, and can be of no use whatever.

Ilford, E., May 1 C. M. INGLEBY

Cross Fertilisation

THE following peculiarities in the flowers of *Helleborus niger* bear upon the same subject as Mr. Hartog's observations on hazel catkins (NATURE, No. 23), and may be worth noticing.

The tubular nectaries by which the petals are replaced are more or less completely hidden by the stamens. The sepals remain for some time half open, and I found that in every case, while the flowers were in this state, pollen readily adhered to the stigmas; and on account of the curved shape of the latter, reaching almost to the half-closed sepals, an insect visiting the nectaries must generally touch them. In such flowers, though the nectaries were full, the anthers had not burst, while in those more fully open, pollen did not so readily adhere to the stigmas, so that in most cases the flowers would be fertilised by pollen from older ones, and probably from distinct individuals. In old and widely-opened flowers, whose anthers had burst, an insect could hardly reach the nectar without being dusted with pollen, while it would probably not touch the stigmas. I may as well mention that I saw a bee visiting these flowers in February last, and in the same month I found a spider in a half-opened flower of *H. fœtidus*.

Mr. Darwin has noticed a case (*Spiranthes autumnalis*, "Fertilisation of Orchids," ch. iii.) in which older flowers are generally fertilised by pollen from younger ones.

CHRISTOPHER J. HAYDEN

Trinity College, Cambridge, April 25

Chamounix

MANY of the readers of NATURE are no doubt preparing for a visit to Mont Blanc; permit me to say to them that the season for making the ascent will, in all probability, be earlier this year than usual, on account of the remarkably fine and hot weather; it is two months within a day or so since any rain fell; but to-day we have had a refreshing shower of three hours' duration, which will prove of infinite service to the little farms in the valleys of Chamounix, St. Gervais, and Sallanches.

Early yesterday morning, accompanied by a guide and my daughter, a nimble girl of 15, I crossed the Glacier de Boissons, at an elevation of 3,000 feet; there was comparatively little snow, the blue ice being repeatedly visible. We made the best of our way up the moraine, and descended through the forest into the valley of Chamounix, where the heat of the sun was oppressive; beetles on the earth and butterflies in the air were numerous.

The cherry, plum, and pear trees, so plentiful near Sallanches, are all in full blossom and doing well—the bees know it.

The ice grotto at the foot of the Glacier de Bois is already diminishing, and a serious-looking crevasse appears at the portal; the *Arve*, which rises from this glacier, is already considerably swollen. Perhaps the most gratifying news to send is the intelligence that the new road from Sallanches to Chamounix is all but finished—a mighty work, worthy of the new ruler of Haute Savoy. S. P.

April 23

PHYSICAL SCIENCE AT CAMBRIDGE

A MEETING of members of the Senate took place here on Saturday last, which is likely to have a considerable influence on the fortunes of Physical Science in this University. About a year ago a Syndicate, or committee of members of the Senate, was appointed to consider in what manner the funds could best be raised requisite for maintaining a Professor of Physical Science, and for providing suitable buildings and apparatus, also for certain other University objects. As the revenues of the University are known to be not more than adequate to maintain the educational machinery already in operation, the appointment of the Syndicate was a tacit adoption of the principle that *College* endowments ought to be made available in order to extend the area covered by professional instruction the advantages of which are open to the members of every college. The Syndicate's report, issued at the end of last term, formed the subject of discussion at the meeting called on Saturday.

The Syndicate informs the Senate that after estimating the sum which would be required to carry out the objects which it was desired to attain, they "decided upon addressing a communication to the several colleges of the University to inquire whether they would be willing, under proper safeguards for the due appropriation of any moneys which might be entrusted to the University, to make contributions from their corporate funds for these objects." The answers to this communication received from the governing bodies of the Colleges are considered as private by the Syndicate, and are not printed in this report. In the opinion of the Syndicate, however, "they indicated such a want of concurrence in any proposal to raise contributions from the corporate funds of Colleges by any kind of direct taxation, that the Syndicate felt obliged to abandon the notion of obtaining the necessary funds from this source." Accordingly they propose another plan for providing the needful funds, or at any rate a portion of them, with which I need not trouble your readers, as it involves technical details, and moreover is in itself so unjust and objectionable that it has not the slightest chance of being adopted.

The one point of real importance on which the discussion on Saturday turned, was whether the Senate ought to acquiesce in the conclusion of the Syndicate, and abandon the notion of obtaining contributions from the corporate funds of the Colleges for University objects. I am glad to be able to inform you that the opinion of the meeting was very decidedly expressed in favour, not of abandoning, but of carrying out this notion. The Master of St. John's said it was a settled matter that the funds requisite for the efficient teaching of Physical Science must be provided by the Colleges, and that the only question was whether they could arrange among themselves some plan for contributing in proportion to their means. Failing this, he held it to be quite certain, that they would be compelled to part with some portion of their corporate revenues for these objects by parliamentary coercion. The Master of Trinity insisted, in the strongest terms, on the urgent necessity of immediate action, if the University was to retain its position in the van of educated opinion. The Vice-Master of Trinity College disputed the statement made by the Syndicate, that the replies of the Colleges were on the whole opposed to making contributions out of their corporate revenues. He said that his own College had at once announced its willingness to contribute, and expressed his belief that a majority of Colleges were in favour of a College contribution, though they were not, as yet, agreed as to the proper principle of assessment. On this point, as the Syndicate has thought fit to withhold from the Senate the answers returned by the governing bodies of the several Colleges to the communication addressed to them, we have no means of forming an independent judgment. Every speaker seemed thoroughly to recognise the urgent and paramount claims of Physical Science to be placed on an effective footing in the University, except indeed the registrars, who urged the superior claims of ecclesiastical history and pastoral theology, and Mr. Perowne, of Corpus, who deprecated exaggerated statements in favour of Physical Science as a disparagement of classics and mathematics, and spoke with effusion of the gratitude which would be earned by "some *rich* College," which should make a present to the University of the funds required, and so save the other Colleges (not so painfully *poor* after all) the pang of putting their hands into their own pockets—a sentiment which drew from Mr. Blore, of Trinity, an amusing sally as to the want of similar benefactors of the common race in the matter of the *Income-tax*.

It seems to be the general impression at Cambridge that the Council will have to appoint a fresh Syndicate to make a second search for a common ground on which the Colleges may be brought to agreement. Meantime, the very general interest excited on the subject throughout the University is an encouraging sign that the just claims of Physical Science will before long be satisfied.

SEDLEY TAYLOR

THE TRANSIT OF VENUS AND THE ANTARCTIC REGIONS

DR. NEUMAYER has recently been in London, looking after apparatus, and making arrangements, for the proposed Austrian expedition preparatory to the one to the Southern Seas for the purpose of observing the Transit of Venus in 1874. The object is one in which every English man of science will feel a warm interest. The lethargy of our own Government has been described by German astronomers and naturalists by the expressive but not complimentary term "Philistinism."

At the sitting of the Vienna Academy of Sciences on March 10th, Dr. Neumayer submitted a proposal for the preparatory arrangements for the observance of the Transit. A map of the circumpolar regions shows that the best points in the Southern Hemisphere for these observations will be the region south of the Indian Ocean, near the circumpolar district. Dr. Oppolzer has established that the most favourable localities for observing the *immersion*, both as to parallax and altitude, can be connected by a curve passing by the great gulf of Australia to the Macdonald Islands, and from these to a point situated in 36° 52′ S. latitude, 43° 23′ E. longitude. The points best adapted for observation of the *emersion* will also be found in a curve passing from the centre of the Indian Ocean to a point situated in 180° E. long., and 79° S. lat.; and from there to another point, 64° 55′ S. lat., and 244° 39′ E. long. The point of intersection of these two curves (48° 5′ S. lat., 99° 3′ E. long.) will evidently be the one most favourable for the observation of the transit in its totality. In this case, the factor of the parallax and of the altitude will be 0°·67, and 48°·0 for the immersion; and 0°·47 and 62°·5 for the emersion. The nearest station to this point will be the Macdonald Islands, situated nearly in 53° S. lat., and 12° E. long. (from Greenwich). M. Neumayer, who visited these islands in 1857, was struck with their relatively high temperature; and has ascertained, by a close examination of the tables of temperature published by the authority of the Dutch Government, that the current of Agulha must terminate near them. The summer and winter isotherms confirm these facts, and there can be no doubt that it is under the meridian of the islands of Macdonald and Kerguelen that the most favourable region must be sought for a route towards the South Pole, in the same manner as Sir James Ross followed, with the same object, a new current which set out from the shores of New Zealand. The map of the southern circumpolar regions, published by Petermann, furnishes very precise information for the equatorial limit of the floating ice, the curve showing two points of depression towards the pole; one under the meridian of Kerguelen's Land, the other under that of New Zealand. It may, however, be said that because floating icebergs have once or twice been found in a locality, these are not sufficient definitely to fix the relations of the floating ice, which depends especially on currents, and which secondary causes, such as winds, can draw into regions ordinarily free of ice. It is the frequency of the ice that must settle the limits in such cases. At the points which have been named the limit of floating ice bends back upon itself as high as 60° S. lat.; and this is an important fact for the determination of the warm currents setting from the north. The position of the limit of maximum density of sea-water, and the presence of spermaceti whales (*Physeter macrocephalus*) which, as is well known, seek in preference warm waters, on the coasts of Termination Land, permit the supposition that the current in question continues towards the South Pole as far as that land and Kemp Island. Admiral Sir John Ross also saw spermaceti whales at the approach towards South Victoria; while Wilkes, Dumont d'Urville, and Ross, only met with few and isolated individuals in the intermediate seas. M. Neumayer thinks that it will be advisable to despatch a small reconnoitring expedition without delay to these regions, and to establish a scientific station on the Macdonald Islands, the first object of which should be to determine the absolute longitude, to serve as a basis for Delisle's method. It would be occupied during the months of November, December, January, and February, with a series of meteorological observations, and with everything relating to physical geography. He proposes that, for this purpose, the Academy should make application to the Government for the fitting out of the expedition, the expense of which would amount to 35,000 florins (87,500 francs.) This has been granted, and the expedition will sail equipped for physical and natural history observations.

THE NATURAL HISTORY OF THE ABYSSINIAN EXPEDITION*

THE Abyssinian campaign will always be an interesting little episode in history. Unlike so many of our military expeditions in bygone times, it was vigorously conceived, energetically carried out, and successfully concluded, and will, we can entertain no doubt, effectively protect us against a repetition of the outrage which led to its organisation. But even if no other advantage resulted from it, the acquirement of so much additional information, both in regard to the zoology and geology of Abyssinia, as is contained in the work before us, would in great measure reconcile all enthusiastic naturalists to the additional trifle of income-tax they have had to pay as their contribution to the expenses of the war; and to all such, we would recommend Mr. Blanford's book, as enabling them at a small outlay to recompense them selves for the annoyance they have experienced.

The author left Bombay for Abyssinia in December 1867, and did not return till the following September, after an absence of nine months and a half, eight of which were spent in Africa. Upon the whole, he appears to have enjoyed unusual advantages in the collection of objects of natural history. He has collected no less than 1,700 specimens of Vertebrata, representing 350 species, besides about 3,500 of Mollusca and Articulata, representing about 500 species. The work is divided into three parts: the first being a personal narrative, the second devoted to the Geology, and the third to the Zoology of the regions traversed.

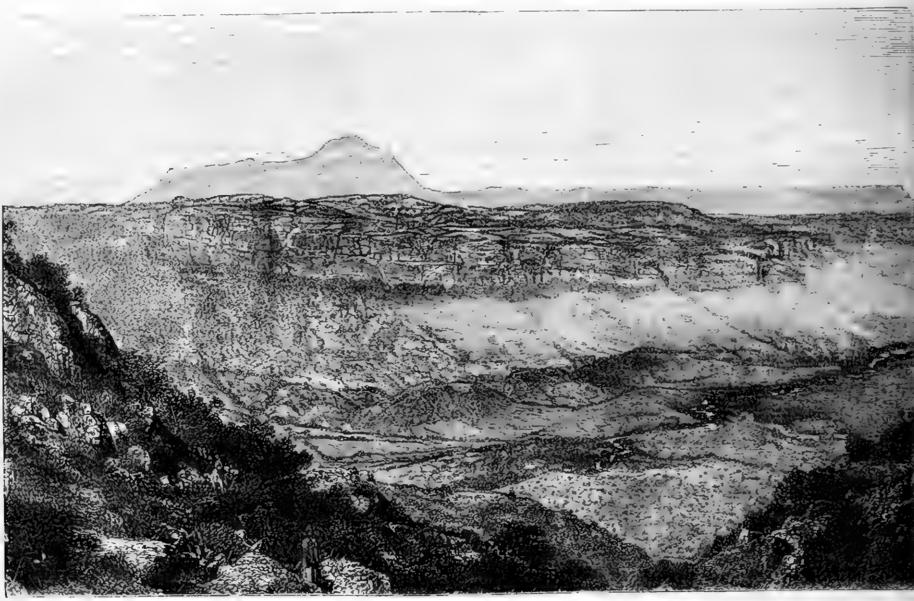
On arriving at Malkatto, in Annesley Bay, he at once set to work to collect specimens. In the vicinity he found larks, chats, shrikes, wagtails, white-breasted crows, kites, and vultures, constituting the commonest land birds, whilst on the shore there were abundance of gulls, pelicans, terns, ring-plovers, curlews, egrets, stints, and sand-pipers, with a little green bee-eater, which frequented the mangroves. Further inland, amongst the thorny acacia trees, he obtained a lovely little Nectarinia, the long-tailed robin, a weaver bird (*Hyphantornis galbula*), and two species of Avadavats (*Pytelia citerior* and *Estrelda rhodopyga*). Amongst the Mammals were hyænas, jackals, gazelles, hares, and Jerboa mice, which, finding unwonted supplies of food in the commissariat stores, increased and multiplied until the ground around the huts and tents was riddled with their holes. The only common reptiles were

* "Observations on the Geology and Zoology of Abyssinia made during the progress of the British Expedition to that country in 1867-68." By W. T. Blanford, F.G.S., late geologist to the Abyssinian Expedition, with illustrations and geological map. (London, Macmillan and Co., 1870.)

a small lizard (a kind of *Acanthodactylus*), and a very venomous little viperine snake (*Echis arenicola*). After the lapse of a few days, he started for the interior, and soon reached Hadoda. On waking the next morning, he saw a large troop of dogfaced baboons (*Cynocephalus hamadryas*), hunting for corn that had been dropped where the horses had been picketed. In the early part of January he was sent forward to examine the water supply, which proved to be abundant, and was obtained in places where there was no running water, by means of Norton's American pumps, and subsequently by an improved kind of chain pump (Brasyer's).

The pass which was selected for the road to the Abyssinian highlands commences at Komayli, situated on the verge of the coast plain, and extends to Senafé, a distance of about fifty miles. At Undul Wells, which is 3,400 feet above the sea, the subtropical fauna was entered, containing some of the animals peculiar to the Abyssinian highlands. Amongst these may be mentioned the *Corvus affinis*, a king crow, a noisy yellow-billed hornbill, a crateropus, a large partridge, and a very handsome bee-eater. A small plain covered with bush jungle, and partly with an aloe-like plant, was haunted with wart-hogs, hyænas, and Beni Israel. At a height of 5,000 feet, the splendid Abyssinian Plantain-eater (*Turacus leucotis*) appeared with a handsome francolin. Senafé itself, at the head of the pass, is 9,050 feet above the sea-level. Here he found the Hyrax, Ichneumon, Klipspringer, and Koodoo.

The drawing shows the Hamas Valley west of Senafé. The lofty hill in the distance is Hasheyat, or, as it is spelt in the excellent geological map which accompanies the work, Kishyat-hill, composed of columnar trachyte, and therefore of volcanic origin. The terrace on the opposite side of the valley is sandstone, while the bottom of the valley lies on metamorphic rocks. The picturesque character of the scenery of this region is here well shown. Leaving Senafé, the road traverses a plain of slaty metamorphic rocks, and presents few points of interest till the valley of Guna Guna is reached, where the scenery becomes very grand, and increases in beauty near Fokada, close to which there is a fine hill of columnar trachyte; and where the road winds round the western side of this, the view over the valley to the westward, exhibited in our second illustration, is one of unusual interest and beauty. The valleys, as usual, are deeply cut into the metamorphics; the flat hill-tops are of sandstone. To the southward, above the sandstone-bed, rise the terraced trap hills of the Harat range, and in the far distance are the strangely-shaped hummocks of the Adowa mountains.



VIEW OF THE HAMAS VALLEY, WEST OF SENAFE

Starting rom Fokada, our traveller, following the track of the army, passed through Adigrat; "a considerable town, with a fine church containing some remarkable mural paintings, in which Scriptural scenes are portrayed as they might have appeared, perhaps, had the scene been Abyssinia and the actors Abyssinians; just as the Italian painters of the Middle Ages introduced the costumes of Italy and the great buildings of Florence and Sienna in the representation of events which occurred in Palestine."

We need not follow Mr. Blanford's progress step by step, as the several camping-grounds are already known to the public through Markham's Abyssinian Expedition, and the correspondent of the *Illustrated London News*.

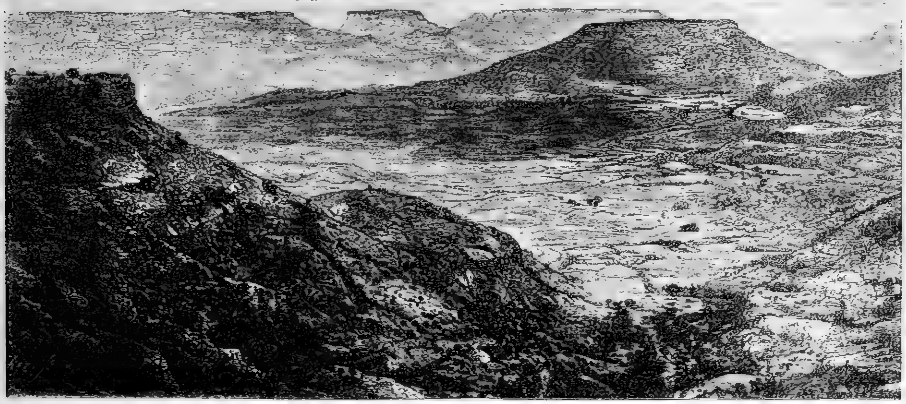
He describes the scenery as being almost everywhere strikingly beautiful; now bold and romantic—now resembling the undulating character of western England.

Near Bethor (not far from Magdala) they came suddenly on the brink of the mighty chasm in which the Jitta river runs, describing which he says,—

"Of all the grand scenery met with in Abyssinia, none equalled this wonderful gorge. It is 3,500 feet deep, and looks scarcely a mile across. The sides are extremely steep, and in places nearly perpendicular. The horizontal beds on both sides appear to correspond exactly. Half-way down there is a well-marked terrace, evidently formed by the same bed on both sides of the river. At the bottom of the ravine ran a beautifully clear stream in a pebbly bed." He entertains no doubt that this gorge has been formed by the river.

Magdala fell on the 16th April, and the retreat was so hasty that Mr. Blanford's opportunities of procuring specimens became much limited, especially as Lord Napier would allow no expeditions into the interior. Meeting, however, at Senafé, on the return journey, with Mr. Jesse, the Zoological Society's naturalist, who had been detained by illness and want of transport, they organised, with Lieut. Mockler, a trip to the Bogos territory, about 100 miles N.W. of Massowah, the details of which form the most interesting part of the work.

At Ailat they found a hot spring, the water with a temperature of 140° F., and perfectly tasteless. Here they had a tragical adventure with a leopard, the details of which are thus given:—"On the early morning of the 29th June, one of my servants rising before daybreak, was scratched in the face by some wild animal which had come into the camp. The track resembled that of a large cat. We thought nothing of this at the time, but on the following night we were all aroused by an outcry and shouting, and an alarm was given that a lion had seized one of our men. Mockler fired off his rifle to frighten away the beast, which rushed roaring past our tent. On enquiry we were horrified to find that an Abyssinian servant of Jesse's had been killed while asleep, and no alarm had been created until the animal attempted to drag away the body. The unfortunate man had two large tooth-holes in his throat, and must have been either so seized that he was unable to cry out, or else, as is probable, his neck was broken. The assailant was doubtless a leopard, very probably the same small animal which had scratched my servant the night before. We had a low thorn fence round three sides of our camp, and the camels occupied the open side—the usual plan in this part of Africa—but we had no fires, a most necessary precaution, and one we never neglected after this sad lesson."



VIEW OF THE PLATEAUX AND VALLEYS WEST OF FOKADA

Subsequently the adventurers had some fine sport with rhinoceroses.

In regard to the Geology of Abyssinia, the various rocks observed in ascending order were: 1, Metamorphic rocks; 2, Adigrat Sandstones; 3, Antalo limestones; 4, Trappean series, including the Magdala and the Ashangi group; 5, the Aden series of Volcanic rocks bordering the Red Sea; and 6, Recent formations—soils of the highlands, coral islands of the Red Sea, and alluvial deposits near the coast.

We need scarcely add that the Zoological portion is carefully drawn up, whilst the plates, which include illustrations of the *Hirundo æthiopica*, *Phylloscopus abyssinicus*, *Ruticula fuscicaudata*, *Pratincola semitorquata*, *Alauda prætermissa*, *Crithagra flavivertex*, and some fossils and horns, are admirably coloured, and very expressive.

NOTES

PROFESSOR STOKES will be a member of the Royal Commission to inquire into the present State of Science in this country. Up to the present time then, so far as we are informed, the Commission stands as follows :—President, the Duke of Devonshire. Members: Professors Huxley, Stokes, and W. A. Miller; Dr. Sharpey, Sir John Lubbock, Bart., M.P.; Messrs. Lyon Playfair, M.P., and B. Samuelson, M.P.

THE following is the list of candidates recommended by the Council for election into the Royal Society:—W. Froude, C.E.; E. Headlam Greenhow, M.D.; J. Jago, M.D.; Nevil Story Maskelyne, M.A.; M. Tylden-Masters, M.D.; A. Newton, M.A.; A. Noble, Esq.; Capt. Sherard Osborn, R.N.; Rev. S. Parkinson, B.D.; Capt. R. Mann Parsons, R.E.; W. H. Ransom, M.D.; R. H. Scott, Esq.; G. F. Verdon, C.B.; A. Voelcker, Ph.D.; S. Wilks, M.D.

AT the meeting of the Royal Geographical Society on Monday Sir Roderick Murchison announced that the Earl of Clarendon had decided, on the part of Her Majesty's Government, to provide means for relieving Dr. Livingstone by land from Zanzibar, news from the doctor having been cut off some time since by the outbreak of cholera on the caravan route. Sir Roderick also announced that the annual general meeting would take place on the 23d inst., and that the Royal gold medals would be awarded to Mr. G. W. Hayward for his journey to Yarkand and Kashgar, and to Lieutenant Garnier, of the French navy, for his merits in bringing the great French expedition from Cambodia to Yangtsin after the death of its chief.

SCIENCE is lively at the Royal Society. Last week we had Principal Dawson's very interesting Bakerian lecture; this week we are to have the Croonian lecture by Dr. Augustus Waller, F.R.S., "On the Results of the Method (introduced by the lecturer) of investigating the Nervous System, more especially as applied to the elucidation of the functions of the Pneumogastric and Sympathetic Nerves in Man." The subject is one of which physiologists will recognise the importance.

THERE is a considerable number of papers on hand at the Royal Society, and there remain but two more evening meetings, May 19, and June 16. The question has been asked whether Dr. Bastian's paper on Spontaneous Generation is to be brought forward at one of those meetings. And the same question might be asked in the case of other papers, and it is not the only question by any means. Were not the present arrangements of the Royal Society (including the break from May 19 to June 16) made to meet a condition of things which has long passed away? And since the flow of papers into the Society has largely increased, why should not the outflow be a little accelerated, and why should not the Bakerian and other lectures be given on extra nights, so that common justice may be done to the authors of other papers? One would have thought that the Royal Society would have gladly hailed the many signs of increased scientific activity, and made arrangements accordingly.

MEDICAL Science has sustained a heavy loss in the death of Sir James Young Simpson, Bart., Professor of Midwifery at the University of Edinburgh, and discoverer of the anæsthetic properties of chloroform. He died on Friday last of disease of the heart, in the 59th year of his age.

M. VILLEMAIN, the Perpetual Secretary of the French Academy, died on Sunday morning last, at the age of 80.

THE practical importance to the State of the progress of scientific discovery was happily illustrated in the debate in the House of Commons on Friday evening last, on the question of opening the Public Galleries during certain hours of the evening. The Chancellor of the Exchequer threw out a suggestion that some mode of lighting might, before long, be discovered as efficacious as gas, and not liable to the objection of endangering the safety of the building. "Science," said he, "was advancing very rapidly, and difficulties which seemed insuperable in these matters to-day, might, if we waited patiently for a few years, be met and overcome." It is needless to point out to so acute a reasoner as Mr. Lowe, that in thus proposing to utilise the possible future discoveries of Science, he furnishes the strongest possible argument for that assistance to Science by the State which we so persistently urge.

IN the same debate Mr. Lowe gave some hope that he might, in the course of the present session, state definitely the views of the Government with regard to the removal of the Natural History collections in the British Museum, a removal which he characterised as a "crying necessity." A considerable space of ground has been purchased by the Government behind the National Gallery, which will be used for some such public purpose.

THE Council of the Scientific Association of France at its last meeting appointed a mixed committee, representing the different branches of science, to perform the functions of the old commissions of astronomy, physics, and meteorology, entrusting to it at the same time the executive power, in the sense of regulating the public sittings, receiving requests for grants, &c. The committee, to which, at its own request, the Council has the power of adding the names of *savants* not belonging to its body, is composed as follows :—Astronomy, MM. Puisseux and Tissot; mechanics, MM. Eichens and Haton de la Goupillière; physics and chemistry, MM. Lissajous, Troost, and Cazin; meteorology, MM. Belgrand and Renou; geography, MM. Mouchez and Ploix; geology and palæontology, MM. Elie de Beaumont and Delafosse; botany, M. Lestiboudoix; zoology and zootechny, MM. Milne-Edwards and André Sanson; agronomy, MM. Payen and Barral. The *locale* of the association is at present at M. Le Verrier's, 1, Rue des Saints-Pères, Paris.

THE discussion which followed Principal Dawson's lecture of which we give an abstract in another column),) was sustained by Sir C. Lyell, Sir R. Murchison, and Dr. Hooker. Sir R. Murchison objected to the adoption of the term "Erian" for the series of pre-carboniferous rocks of North America, corresponding to our Devonian or Old Red Sandstone, as an unnecessary innovation; while Dr. Hooker thought that caution was necessary before concluding that the apparently exogenous fragment of wood found in a bed occupying the centre of the "Erian" series must necessarily belong to a dicotyledonous tree. He considered it quite possible that the structure of the wood of some of the higher Cryptogams of this early period might closely resemble that of dicotyledonous Phænogams.

WE print the following note from St. John's College, Cambridge :—"The following have been placed in the first class of the college examination in Natural Science: Blunt, Garrod, and Read. The names are arranged in alphabetical order, and the examiners are the same as for the open exhibition adjudged on Friday last. The second-class contains four names, and the third three."

THE fiftieth anniversary of the Leeds Philosophical and Literary Society was commemorated during last week, in the usual English manner, by a dinner.

THE following Special Meetings of the Ethnological Society will be held during the month of June :—Wednesday, June 1st, at the Royal United Service Institution, Whitehall-yard; "Report on the Prehistoric Antiquities of Dartmoor," by Mr. C. Spence Bate, F.R.S. Tuesday, June 7th, at the Museum of Practical Geology, Jermyn-street; "On the Geographical Distribution of the chief Modifications of Mankind," by Prof. Huxley, President. Tuesday, June 21st, at the Royal United Service Institution, Whitehall-yard; "On the Aymara Indians of Bolivia and Peru," by Mr. David Forbes, F.R.S. The meetings will commence punctually each evening at 8.30 P.M.

THE planet Lydia (No. 110), discovered by M. Borelly at the Marseilles Observatory on the 19th of April, had at $10^h33^m13^s$ mean Marseilles time, the following position:—Right ascension $12^h2^m39^s{\cdot}22$; north declination $6^\circ50'38''{\cdot}8$. Its horary motion has been determined as follows:—In right ascension $-1^s{\cdot}77$, in declination $+2''{\cdot}20$; its magnitude is between 12 and 13. M. Borelly had previously discovered two planets, bearing the numbers 91 and 99 in the system of asteroids revolving between Mars and Jupiter. These two planets had long been nameless, in consequence of the persistent refusal of M. Le Verrier to permit the astronomers under his jurisdiction to bestow any name upon them. The 91st has now received the name of Egina, the 99th that of Dikë.

THE planet which bears the number 109 in the series of asteroids, and which was discovered at Clinton by Mr. C. H. F. Peters, on the 9th of October last, has received the name of Felicitas. The following are the new elements of its orbit, which have been calculated by Mr. William A. Rogers, from three positions, on the 9th of October, 28th of November, and 22nd of January last:—

Epoch: 1869; Oct. 9th, mean Washington time.

Mean anomaly	$339^\circ\ 5'\ 45''{\cdot}21$
Longitude of perihelion	$55\ 56\ 3\ {\cdot}35$
Longitude of ascending node	$4\ 56\ 4\ {\cdot}35$
Inclination	$8\ 2\ 56\ {\cdot}10$
Angle (sine = eccentricity).	$17\ 27\ 2\ {\cdot}67$
Logarithm of half of the greater axis	$0{\cdot}4304068$
Mean diurnal motion	$802''{\cdot}41019$

WE have received the first sheet of Messrs. W. and A. K. Johnston's new Illustrations for Botanical Lectures, selected and arranged by Professor Balfour. It is occupied with a general ideal drawing of the various organs of a plant; and with illustrations of the embryo plant, cells and vessels, root and stem. If the series fulfil the promise of the first sheet, it will supply a desideratum for the botanical lecturer. The sketches are clear and well executed, and if they are too crowded, it is difficult to see how this could be avoided without making the series of an unwieldy size. We would suggest that their utility would be increased if they are also issued in sheets and uncoloured. The setting on a roller is not always the most convenient, and many would be glad to save the expense of the colouring. The descriptive pamphlet of text accompanying the sheet, by Professor Balfour, is in itself almost an elementary handbook of botany.

IN the last report of the Registrar-General, he gives a valuable classification of the geographical distribution of various diseases in the different districts of England, and concludes by remarking: "It is true that the returns of deaths can never furnish such immediate notice of the origins of epidemic diseases as returns of cases of disease; but it is not true that the information of the death register is necessarily too late; it is too late as regards the individual, but it is not too late as regards the community, which can immediately adopt measures to quench the sparks before they involve it all in flames. The seas which divide this island from the rest of the world no longer ward off diseases, which are landed every day on her shores, and can no more be shut out than the east winds. The nation is associated with all races and nations by its maritime population, and with many by empire. And however much men may indulge the natural pride of nationality, in one respect their solidarity admits of no dispute; they are all subject to the same diseases, and are all interested equally in the mitigation of the sufferings and losses those diseases occasion. How can those evils be mitigated unless their origin is known, and unless science determine the laws by which they are governed? And recorded observation on a European scale is as necessary for the determination in this field of life as observation of the skies in astronomy, without which Copernicus, Newton and Laplace could never have built up the system of the universe, or have given the navigator the means of avoiding shipwreck and finding his destination over the ocean. England is the only country in the world at the present time which publishes weekly and quarterly observations on an extensive scale in time to be available for immediate administrative use. But the Registrar-General hopes soon to get the co-operation of other countries, and in a few years to see in operation among several of the principal nations of the world one well-concerted series of reports of their marriages, births, deaths, and most controllable diseases."

IN the *séance* of the 11th April M. Duchemin brought before the Academy of Sciences of Paris the following curious fact in Natural History:—In the park of the Château de Montigny (Eure) belonging to M. Deroche, there is a large piece of water, through which a gentle current of beautifully clear water flows. In this lake numerous carp are reared, which thrive well, except during the first days of spring, when each year an extraordinary mortality occurs amongst them. In each animal one morbid symptom is always observable in the dead animals as they float on the surface of the water. In every case the animal is blind; a kind of film covers the eyes and even a part of the head. An examination of the body brings to light no internal disease, beyond a slight fatty degeneration of the tissues. The viscera appear healthy, and contain no intestinal worms. The cause of this strange malady has not hitherto received any notice; but from M. Duchemin's researches, in conjunction with M. Deroche, it seems that the toad (*Bufo calamita*) is an enemy, if not of all fishes, at least of the carp in spring. It attacks it, exhausts it, conquers, and kills it. To determine the point, they examined all the carp in the pond, and found squatting on the head of each of those that were diseased an enormous toad, the fore-paws of which were placed on the two eyes of the unfortunate fish. Thus, this ugly Batrachian, which presents so stupid an aspect, has yet sufficient intelligence to assume the offensive, and to overcome a large fish. If it has not agility and energy, it has cunning and perseverance. It would appear to kill by exhaustion, but it remains to be ascertained whether the acrid secretion of its skin assists in the conquest.

IN a still more recent *séance* of the Academy of Sciences, M. Duchemin, reverting to the above communication in regard to the mortality of the carp being in some instances due to the attacks of the toad, supplies observations which have been forwarded to him in support of his statements, and relates that from investigations undertaken at the Château de Montigny, the toad does not always remain permanently fixed on the head of the dead fish, but only so long as it gives signs of life. He observes, too, that all the carps from which the attacking toads had been removed were more or less blind. They were placed with care in another pond, but none of them recovered from the injuries received. No author has hitherto noted this animosity of the toad for the carp, who perhaps themselves consume the eggs of the toad. He has obtained additional evidence from M. Mermet, Directeur des Eaux at Contrexville (Vosges), who states that it has been found impossible to preserve carp in a sheet of water in that neighbourhood in consequence of the presence of numerous toads. M. l'Abbé Caillet, Curé of Rosoy (Haute Marne), whilst confirming the above statements, writes to him, "The toad is a villanous beast. One day I observed one that had crawled beneath a hive. There, with his two forepaws advanced and his throat wide open, he attracted the innocent bees, with which his sides were distended."

THE traffic of the Tower Subway—of the engineering features of which we recently gave an account (see NATURE, Vol. i., No. 11, p. 280)—has not been proceeding very smoothly, owing, we think, to defects in its management, and indeed was altogether suspended for a week or two. The passage through the tube is stated to be often interrupted by the breakage of the wire rope; for this purpose two engines are used, one at each end of the tunnel, while the obvious and ordinary arrangement would be to employ only one engine driving a shaft with two drums and an endless rope. The arrangements might be very similar to those adopted in mines for raising and lowering the "cage," except that in this case the cage would be the carriage, and would travel on nearly a level line instead of up and down a shaft. The mode adopted for raising and lowering passengers in the shafts attached to the subway is by means of a chain which draws the carriage up and down, various "safety" arrangements being adopted in case of the giving way of the chain. For raising and lowering passengers, a chain or rope is not however the best means. In the apparatus in use in all the best hotels in America, there are no chains or ropes, no catches, springs, or buffers in case of accident. There is a vertical hollow cast-iron column reaching through the whole length of the shaft; in that shaft is the thread or helix of a screw projecting a couple of inches from its surface; the cage forms part of the nut, which rests in the screw or shaft. The shaft is turned by a small engine, controlled by the guard, who travels with the cage; he can moderate, stop, or reverse the motion, and accidents in the ordinary sense are out of the question. It will thus be seen that the problems to be solved as to the best means of transporting passengers through the Tower Subway are of the simplest kind.

WE understand that the late Mrs. Appold has left to the Institution of Civil Engineers, a legacy of 1,000*l*., payable at the same time as the legacy for a similar amount from her husband, the late Mr J. G. Appold, F.R.S., Assoc. Inst. C.E. It is believed that both bequests have been made "for the general use and benefit of the Society," without being fettered with any conditions.

To those of our Scientific Societies who annually assure themselves, and others, of their continued existence by a dinner, we commend the "Report of the Speeches at the Annual Dinner of the Institution of Civil Engineers, May 4, 1870," which we have just received,—as an indication of what a little energy can make even of a dinner. Professor Tyndall answered for Science, showing in a clear way how physical research lies at the root of all conquests of Nature, gaining help in turn from the practical man. "Thus does the human intelligence oscillate between sound theory and sound practice, gaining by every contact with each an accession of strength. These two things are the soul and body of science, as far as you and I are connected with it. Sever sound theory from sound practice, and both die of atrophy. The one becomes a ghost, and the other becomes a corpse."

WE have received the first and second volumes of Dr. L. Lindenschmit's "Die Alterthümer unserer heidnischen Vorzeit," from originals in public and private collections, published under the authority of the Roman-German Central-museum at Mayence. The illustrations are most copious, and the work admirably done.

DR. R. CASPARY reprints from the Transactions of the Natural History Society of Halle a paper on the genus *Nuphar*. In examining the water-lilies of the Black Forest, as well as of Prussia and other districts of Northern Europe, he finds an intermediate form between *Nuphar luteum* and *N. pumilum*, which he regards as a true natural hybrid between two distinct species, and not as a mere transitional form. Another reprint from the Transactions of the same society is an essay on the Lennoaceæ, by H. Graf zu Solms-Laubach.

KONER'S *Zeitschrift der Gesellschaft für Erdkunde zu Berlin* contains a number of most valuable geographical papers, accompanied with carefully-executed maps; and a list of all geographical works, maps, and plans in all languages published between December 1868 and November 1869.

THE PHYSICAL CONSTITUTION OF THE SUN

DR. GOULD has addressed an important letter on the above subject to the Journal of the Frankland Institute. In the first part he refers to the new light recently thrown on the sun's physical constitution by the observations of Mr. Lockyer, and agrees with him and Dr. Frankland, both as to the absorption taking place in the chromosphere and photosphere itself, and also as to the possible telluric origin of the corona.

He then proceeds with regard to the probable age of the sun:—

"The researches of Helmholtz and Thomson regarding the age of the sun as a source of cosmical heat have shown us limits within which, in the absence of more decisive evidence, we must restrict our theories as to the length of time during which he has warmed the earth. The contraction-theory has been most ably discussed by these eminent physicists, and seems to afford the only satisfactory mode of accounting for the solar light and heat, now that we know both that the meteors generally revolve in cometary orbits, and that the habitability of the earth, as well as the apparent unchanged mutual attraction of the planets, bears testimony to the incorrectness of the meteoric theory. From Pouillet's data (derived from experiments which ought to be repeated in some year when the solar spots are at a minimum) Helmholtz has shown that, even were the sun's density uniform, a contraction of $\frac{1}{10}$ per cent. in his diameter would evolve 20,000 times the present annual supply of solar heat. But when the sun was hotter the same proportional contraction would have evolved yet more heat; so that we must consider the above estimate as a minimum.

"The expansibility of hydrogen gas for 100° C. is 0·3661. No gas appears to have so small a coefficient as 0·360, which would correspond to a linear expansion of 0·108. The expansibility of glass, the smallest known, I believe, even for a solid, is about $\frac{1}{150}$ part as great; say 0·00244 in volume, or 0·00081 linear. Therefore for glass even, a contraction of 1 per cent. in diameter would imply a fall of temperature by 1230° C., and a mean specific heat of 218. This seems certainly a minimum value.

"But if we suppose the expansion coefficient to be as large as that of hydrogen, a contraction of 1 per cent. would correspond to a change of temperature by 8·2° C. or a mean specific heat of 32,700, if equivalent to 20,000 years' supply. This is out of the question.

"Now Thomson has computed that bodies smaller than the sun, falling from a state of relative rest at mutual distances which are large in comparison with their diameters, and forming a globe equal to the sun, would generate 20,000 times the present annual supply. This would be greater did we consider the unquestionable increase of the sun's density towards his centre. And since it seems out of the question that resistance and previous minor impacts could have consumed more than one-half the heat, he inferred ten million times a year's supply to be the lowest, and one hundred million times to be the highest, estimate of the sun's initial heat.

"Now we have every reason for the belief that radiation is proportional to temperature. Assuming this and taking the temperature of the sun's photosphere as 14,000° C.,

10,000,000 times the present annual supply would be radiated
in 3,650,000 years if the specific heat were 218,
in 7,280,000 ,, ,, ,, ,, 1000.
100,000,000 times the present annual supply would be radiated
in 8,250,000 years if the specific heat were 218,
in 25,500,000, ,, ,, ,, ,, 1000.
500,000,000 times the present annual supply would be radiated
in 11,700,000 years if the specific heat were 218,
in 38,900,000 ,, ,, ,, ,, 1000.

"For vapours, other than hydrogen, the greatest known specific heat, so far as I am aware, is 0·508 (ammonia); and hydrogen, which has less than 3·5, cannot form any considerable portion of the sun's mass.* A specific heat so high as 1,000 seems altogether out of the question; yet it will be seen that, even on this supposition, an amount of initial heat equal to 500,000,000 the present annual supply, would have been radiated in less than forty million years, were the sun's radiative capacity proportional to his temperature. Taking the more probable age, 10,000,000 years, we should find 226 million times the present annual supply to have been radiated within this period if the specific heat were not greater than 218; and even were the specific heat 1,000, the total radiation would have been eighteen million times a year's radiation at present.

* It seems to form certainly not more than the 18,000th part of the mass of the earth.

"Thus the limit given by Thomson, although so vastly below that afforded by the speculations of some geologists, would appear itself to demand a considerable additional reduction. And I cannot see how we can well suppose the sun in its present form to have radiated heat for more than twenty millions of years, while three or four millions would seem to be a far more probable estimate, unless the thermic laws be totally different in those exalted temperatures which we must suppose to have existed at some past epoch.

"The very great diversity of the limiting values for the specific heat seems to afford ample scope for every needful allowance on account of the natural action of the particles within the body of the sun, even conceding to this the immense effect (analogous to the increase of specific heat) which has been assigned to it by some investigators. Even did we conceive a primitive heat equal to 200,000,000 times the amount now yearly radiated, and a specific heat 10,000 times as great as is possessed by any known gaseous body excepting hydrogen, we could not deduce so long a period as 80,000,000 of years for the past duration of the sun's heat."

SCIENTIFIC SERIALS

THE *Geological Magazine* for May (No. 71, or Vol. vii., No. 5) commences with a biographical sketch of Mr. G. Poulett Scrope, whose investigations into the phenomena of vulcanicity certainly entitle him to a distinguished place among eminent living geologists. This article is illustrated with an admirable portrait. Mr. Jenkins communicates an article on the surface geology of Belgium, in explanation of his map, a reprint of which appeared in the April number of the magazine. Mr. Maw notices two sections on the borders of Shropshire and Cheshire, in which Rhætic beds with characteristic fossils are exposed. In a paper on the Lower Silurian rocks of Galashiels, of which only the first part, illustrated with a map, is here published, Mr. Lapworth furnishes an important contribution to the elucidation of this confused group of rocks. The article in this number which will be generally read with most interest is one by Mr. James Croll, upon the boulder clay of Caithness, which he maintains to be a product of the action of land ice. This paper also is incomplete. Professor Rupert Jones notices and figures the species of Entomostraca from the coal measures of South Wales; several of the species are described as new. Lastly, Mr. Judd's paper, on the use and application of the term Neocomian, contains a good discussion of a matter which, although it seems to be merely a question of terminology, is really, especially at the present moment, one of considerable importance to geologists. Besides the usual reviews, notices, &c., the present number contains a supplementary paper by Mr. Samuel Hyde, on deep-mining in the south-west of Ireland, which possesses much economical interest.

THE *Ibis*, a Quarterly Journal of Ornithology, New Series, No. 22, April 1870. (Van Voorst.)—This number contains :—(10) "Notes relating chiefly to the Birds of India," by Mr. Blyth—the results of an examination of the specimens in the Leyden Museum; (11) "Note on the Systematic Position of *Indicator*," by Mr. P. L. Sclater; (12) "Stray Notes on Ornithology in India," by Mr. Allan Hume; (13) "On New and Little-known Birds collected during the Voyage of the *Magenta*," by Drs. Giglioli and Salvadori; (14) "A List of the Birds of Turkey" (continued), by Capt. Elwes and Mr. T. E. Buckley; (15) "On Rare and Little-known *Limicolæ*," by Mr. J. E. Hasting, determining and discriminating two puzzling species of *Eudromias*, *E. asiaticus*, and *E. veredus*; (16) "On the *Oriolidæ* of the Ethiopian Region," by Mr. R. B. Sharpe—a very elaborate article; (17) "On the Ornithology of Hainan" (continued), by Consul Swinhoe; (18) "On existing Remains of *Alca impennis*," by Prof. Newton, showing that there remain to us of this supposed extinct bird 71 or 72 skins, 9 skeletons, detached bones of 38 or 41 individuals, and 65 eggs. (19) "Notices of Recent Ornithological Publications"—English, French, Dutch, German, Russian, and American, wherein more than twenty works are briefly reviewed; and (20) "Letters, &c.," from Messrs. Layard, Hume, Brooks, and R. Gray, Col. Tytler, Lord Walden, Mr. C. Horne, Capt. Fielden, Herr von Pelzeln, Dr. Salvadori, and Messrs. P. L. Sclater, Harvie Brown, Hawkins, H. Saunders, Elliot, Tristram, and Skeat—the last a communication which will interest others than ornithologists, for it explains the etymology of the name "Grey Lag Goose"—the goose that *lagged* behind the others bred in this country when its congeners had departed for their summer quarters. The number is illustrated by some woodcuts, and by five beautiful coloured plates, by Mr. Keulemans, representing eight species of birds, of which six have never been figured before, and the other two in imperfect plumage only.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 5.—The Bakerian Lecture, "On the Pre-Carboniferous Floras of North-Eastern America, with especial reference to that of the Erian (Devonian) Period." By J. W. Dawson, LL.D., F.R.S., &c., Principal and Vice-Chancellor of M'Gill University, Montreal.

The attention of the author was first directed to the Devonian as distinguished from the Carboniferous flora, by the discovery, on the part of Sir W. E. Logan, in 1843, of some remarkable remains of plants in the Sandstones of Gaspé, Canada. In 1859, after visiting Gaspé to study these plants *in situ*, descriptions of them, and more particularly of the two characteristic Lower Devonian genera *Prototaxites* and *Psilophyton*, were published in the Journal of the Geological Society. Subsequently additional material was obtained by personal investigation of the Devonian of Maine and New Brunswick, and through the kindness of Prof. James Hall, from that of New York. These additional plants were also published in the Journal of the Geological Society. Still more recently, a thorough re-examination of the Gaspé beds, the systematic exploration of the plant-bearing beds near St. John by Prof. Hastt, and fresh collections made by Prof. Hall, have enabled the author to prepare a catalogue of 121 species, and to attempt a thorough revision of the Erian flora, and an investigation of its conditions of growth and relations to the Carboniferous flora.

The term "Erian" is applied to the formations included between the top of the Upper Silurian and the base of the Carboniferous, on account of the uncertainties which have attended the subdivision and limitation of the Devonian of Europe, and also on account of the immense area occupied by these beds on the south and west of Lake Erie, and their admirable development with regard to subdivisions and fossils. The name "Erie Division" was also that originally applied to this typical series by the geologists of the Survey of New York.

A large part of the paper was occupied with the revision of the Erian flora, including the description of twenty-three new species, and more ample descriptions of others previously known only in fragments. Large trunks of *Prototaxites*, from the base of the Lower Devonian, were described, and full details given of the form, structures, and fructification of two species of *Psilophyton*. The new genus *Ormoxylon* was described. The genus *Cyclostigma* was noticed, as represented by two species in America, and its foliage and fruit described for the first time. The genera of the Erian Ferns were examined and corrected, and several interesting trunks and stipes belonging to Tree-ferns were described. The fruits of the genus *Cardiocarpum* were illustrated with reference to their structure. The occurrence of *Lepidophloios*, *Calamodendron*, and other forms in the Middle Devonian was noticed for the first time.

The third part of the memoir was occupied with comparisons and general conclusions. At the close of the Upper Silurian period there was a great subsidence of the land in Eastern America, proved by the wide extent of the marine beds of the Lower Helderberg (Ludlow) group. It was on the small areas of Lower Silurian and Laurentian land, remaining after this subsidence, that the oldest land plants known in the region flourished. Re-elevation occurred early in the Devonian period, and the known flora receives considerable extension in the shallow-water beds of the Lower Erian. The subsidence indicated by the great Carboniferous limestone interrupted these conditions on the west side of the Appalachians, but not on their eastern side. At the close of this we find the rich Middle Devonian flora, which diminishes toward the close of the period; and after the physical disturbances which on the east side of the Appalachians terminated the Erian age, it is followed by the meagre and quite dissimilar flora of the Lower Carboniferous; and this, after the subsidence indicated by the Carboniferous limestone, is followed by the Coal-formation flora.

If we compare the Erian and Carboniferous floras, we find that the leading genera of the latter are represented in the former, but, for the most part, under distinct specific forms; that the Erian possesses some genera of its own, and that many Carboniferous genera have not yet been recognised in the Erian. There is also great local diversity in the Erian flora, conveying the impression that the conditions affecting the growth of plants were more varied, and the facilities for migration of species less extensive than in the Carboniferous.

In comparing the Erian flora of America with the Devonian of Europe, we meet with the difficulty that little is known of the plants of the Lower and Middle Devonian in Europe. There are, however, specimens in the Museum of the Geological Survey which show, in connection with facts which can be gleaned from the works of continental writers, that *Psilophyton* occupied the same important place in Europe which it did in America; and in the Upper Devonian the generic forms are very similar, though the species are, for the most part, different.

In Eastern America no land flora is known below the Upper Silurian; and even in that series the plants found are confined to the genus *Psilophyton*. Independently, however, of the somewhat doubtful Lower Silurian plants stated to have been found in Europe, there are indications, in the Lower Erian flora, that it must have been the successor of a Silurian flora as yet almost unknown to us; and the line of separation between this old flora and that of the Devonian proper, seems to be at the base of the Middle Devonian.

In applying these facts and considerations to the questions relating to the introduction and extinction of species, and the actual relations of successive floras, it was proposed to compare what might be called specific types, that is, forms which in any given period could not be rationally supposed to be genetically related. Of these specific types, at least fifty may be reckoned in the Erian flora; of these, only three or four are represented in the Carboniferous by identical species, while about one half are represented by allied species. The remainder have no representatives.

A Table of specific types of the Erian was given, and its bearing shown on the questions above referred to; and the hope was expressed that by separating such types from doubtful species and varietal forms, some progress might be made towards understanding, at least, the times and conditions in which specific types were introduced and perished, and the range of varietal forms through which they passed.

Royal Institution, May 9.—Sir Henry Holland, Bart., F.R.S., president, in the chair.—T. W. Boord, F.S.A., Miss Eliza Bowman, Miss Margaret Graham, Rev. Brenchley Kingsford, M.A., H. F. Makins, R. Heber Prance, the Earl of Rosse, F.R.S., the Hon. Capt. R. Talbot, M.P., the Hon. P. S. Wyndham, M.P., were elected members of the Royal Institution. John Tyndall, LL.D., F.R.S., was re-elected as Professor of Natural Philosophy.

Geological Society, April 27.—R. A. C. Godwin-Austen, F.R.S., vice-president, in the chair. The following communications were read:—1. "On the species of rhinoceros whose remains were discovered in a fissure-cavern at Oreston in 1816." By George Busk, F.R.S., F.G.S. The object of this paper was to show that the rhinoceros whose remains were discovered by Mr. Whidbey in a fissure-cavern at Oreston, near Plymouth, in the year 1816, and described by Sir Everard Home in the "Philosophical Transactions" for 1817, belonged, not as has hitherto been supposed by every one except the late Dr. Falconer, to *Rhinoceros tichorhinus*, but to *Rh. leptorhinus*, Cuv. (*R. megarhinus*, Christol). The remains in question are in the Museum of the Royal College of Surgeons, and consist of between thirty and forty, more or less, broken portions of the teeth, and of numerous bones of the skeleton. The greater number being hardly in a condition to afford satisfactory diagnostic specific characters, the remarks in the paper were limited to the teeth and to a perfect metacarpal bone, which appeared amply sufficient for the purpose. The teeth mainly relied upon were the first or second upper molars (m^1 or m^2) of the right and left sides. Both the teeth were broken, but what was wanting in one was supplied by the other. The characters exhibited were shown to be unlike those of *R. tichorhinus*, and quite in accordance with those of *R. leptorhinus*. These were the thinness and smoothness of the enamel, the configuration of the dorsal surface, the form and size of the columns, and the disposition and relations of the "uncus" and "*pecten*" ("*crochet*" and "anterior combing-plate);" and the consequent absence of the characteristic "*tichorhine pit*" or *fossette*. The less strongly marked characters by which the teeth could be distinguished from those of *R. hemitœchus*, Falc., and *R. etruscus*, Falc., were also pointed out. The metacarpal bone selected for the illustration of the diagnosis is 9½ inches long, and remarkable for the compression of the shaft and its comparative slenderness, as contrasted with the same bone in *R. tichorhinus*, specimens of which were exhibited on the table, and which, in no case within the author's knowledge, ever exceeds 7½ or 8 inches in length, and is proportionately much thicker than in *R. leptorhinus* or any other extinct species. The size and form of the bone also showed that the species could not be either *R. hemitœchus* or *R. etruscus*, for although the means of direct comparison with the third metacarpal of those species did not, to the author's knowledge, exist in London, its probable general dimensions and proportions could be deduced from those of the corresponding metatarsal, of which bone numerous specimens were available. It was further shown that the Oreston metacarpal exactly corresponded with those of *R. leptorhinus*, from Grays Thurrock, in the British Museum. The determination of the species appears to be of considerable interest, inasmuch as it affords an additional instance of the occurrence in England of the great southern Rhinoceros. This is also the only example of the discovery of that species, except in river or other deposits, either in this country or on the Continent. The Chairman remarked that at one time the Oreston *Rhinoceros* was referred to *R. tichorhinus*, but that Buckland, although mentioning the *Rhinoceros*, never gave it a specific name. The Chairman also said that the Oreston fissures were not caves, but mere fissures which had been filled in; an entire skeleton occurred at one spot, and the animal must have fallen in. Mr. Boyd Dawkins had been struck by the non-tichorhine character of the Oreston specimens some years since. He confirmed Prof. Busk's determination, and remarked that five British species of *Rhinoceros* are known, namely: 1. *R. Schleiermacheri*, from the Red Crag of Suffolk (in the Miocene at Darmstadt); 2. *R. etruscus*, from the Forest Bed = *R. Merckii* (Von Meyer); 3. *R. megarhinus* (Christol) = *leptorhinus* (Cuv.); but the latter name includes also *R. etruscus* and *R. hemitœchus*; so that the adoption of De Christol's name gets rid of a difficulty; 4. *R. hemitœchus*; and 5. *R. tichorhinus* = *R. antiquitatis* (Blum.). Prof. Busk, in reply, stated that Oreston was a fissure-cavern, and noticed the successive openings in 1816, 1821, and 1826. He did not agree with Mr. Boyd Dawkins in preferring the name *megarhinus* to Cuvier's *leptorhinus*. He did not know of the occurrence of two species of *Rhinoceros* at Oreston.

2. "On two Gneissoid series in Nova Scotia and New Brunswick, supposed to be the equivalents of the Huronian (Cambrian) and Laurentian." By H. Youle Hind, M.A.

This paper described the relations of two gneissoid series in Nova Scotia and New Brunswick, which have hitherto been regarded as intrusive granites and syenites, and have been thus represented on the published geological maps of those provinces. The author considered that these gneisses were in the main of Laurentian age, the Huronian or Cambrian rocks occurring only in patches over a vast area of Laurentian porphyroid gneiss. The old gneiss was stated to be brought to the surface by three great undulations between the Atlantic coast of Nova Scotia and the Laurentian axis of America north of the St. Lawrence. These axes were rudely parallel to one another, and in the troughs which lay between them the Silurian, Devonian, and Carboniferous series occurred in regular sequence, the New Brunswick Coal-field occupying the central trough. On the line of section, in the troughs to the north-west and south-east, the Lower Carboniferous was stated to be the highest rock series which has escaped denudation. The gold-bearing rocks of Nova Scotia are of Lower Silurian age, and rest either on Huronian strata or, where these had been removed by denudation, on the old Laurentian gneiss. The gold is found chiefly in beds of auriferous quartz of contemporaneous age with the slates and quartzites composing the mass of the series, which, in Nova Scotia, is 12,000 feet thick; and the auriferous beds are worked, in one district or another, through a vertical space of 6,000 feet. Besides auriferous beds of quartz, intercalated beds and true veins are found to yield gold, and are worked. A series of sharp and well-defined anticlinals ridge the province of Nova Scotia from east to west, while another series of low broad anticlinals of much later date have a meridional course. At the intersection of these anticlinals the gold districts are situated, because there denudation has best exposed the upturned edges of the auriferous beds of quartz, and rendered them accessible, sometimes exposing also the underlying gneiss. Plans of Waverley and Sherbrooke gold districts were exhibited, showing the outcrop of the edges of the slates and auriferous beds of quartz in semi-elliptical forms, with the gneiss at the base of the ellipse. On this ground it was suggested that a correct mapping of the gneisses of Nova Scotia would have an important influence on the development of the mineral resources of the province. A plan of some of the lodes in the Waverley gold district showed the result of operations in 1869, subsequently to the publication of a geological map and sections of the district furnished to the Department of Mines by the author in 1868. Citations were made from the annual reports just issued of the Chief Commissioner of Mines and of the Inspector of Mines, confirming the correctness of the author's plans exhibiting the geological structure of Waverley, which is a type of all the Nova Scotian gold districts. Principal Dawson spoke in confirmation of the fact that the Palæozoic rocks are underlain by Laurentian gneiss, &c., quite to the eastern coast of British North America, and stated that the same relation occurred in Newfoundland, and had been traced southwards into Massachussetts. He confirmed Mr. Hind's views generally, and stated that the Lower Silurian of Nova Scotia includes no great fossiliferous limestone, like that of the interior of North America. The supposed *Eozoon* discovered by Dr. Honeyman, was probably distinct from *E. canadense*, but was certainly a Foraminiferal organism allied to *Eozoon;* but as *Eozoon bohemicum* is of later date than *E. canadense*, the presence of *Eozoon* did not necessarily indicate Laurentian age. Prof. Ramsay suggested that other organisms besides *Eozoon* aided in building up these great calcareous masses. He inquired as to the mode of occurrence of gold, and suggested that the gold is obtained at the anticlinals merely because the exposure is better, and that it will be found to pervade the synclinals also. Mr. Henry Robinson had visited the Waverley district in company with Prof. Hind, in the winter of 1868, at which time the mining on the lodes referred to in the map before the society was at a standstill, the lodes having been lost by reason of a fault. He thought it was very satisfactory to find that the explorations of Prof. Hind, and the theoretical position which he assigned to the lodes, had been completely verified. Mr. Robinson also stated that gold is being mined in the synclinals by sinking shafts and driving cross-cuts. Mr. Hind remarked that all the Lower Silurian in Nova Scotia was auriferous, and that the gold was derived from the underlying Laurentian rocks. He stated that Sir W. E. Logan had indicated an auriferous zone in the Laurentian of Canada. Gold was finely distributed in the slates of Nova Scotia, as in Victoria, in the neighbourhood of lodes, according to Mr. R. Brough Smyth.

Chemical Society, May 5.—Prof. Williamson, F.R.S., President, in the chair. The following gentlemen were elected fellows: G. Matthey, T. Steel, T. Allen.—Mr. Brown read a paper on "Vapour densities," wherein he gave a historical review of the various methods employed for the determination of such densities.—Mr. Church communicated the analyses of two Cornish minerals. The one, Restormelite, may be regarded as a variety of kaolinite, standing nearest to the lithomarge group. The analysis gave the following figures:—

H_2O	11·68	per cent.
SiO_2	45·21	,,
Fe_2O_3	1·11	,,
Al_2O_3	35·10	,,
MgO	0·85	,,
K_2O	2·30	,,
Na_2O	4·12	,,

This corresponds pretty well with the formula of kaolinite, Al_2O_3, $2\ SiO_2+2$ aq., if we suppose a partial replacement of hydrogen by sodium or potassium, and of aluminium by iron. Restormelite may be considered as preserving in its alkalies more evident traces of its feldspathic origin than are usually found in such alteration products. The second of the above-mentioned minerals is Chalcophyllite. The recorded analyses of this mineral were so unsatisfactory that Mr. Church thought it worth his while to submit to a new investigation. The figures he obtained in his analysis led him to assign to chalcophyllite the formula $8\ CuO$, $Al_2\ O_3$, $As_2\ O_5 + 24$ aq. The mineral cannot be dried even in vacuo without an entire change in its appearance. The beautiful green and transparent crystals become of a more bluish tinge, and quite opaque. This change corresponds to a loss of 13·79 per cent. of water.—Messrs. Bolas and Gloves communicated a paper on their newly-discovered tetrabromide of carbon. This compound is obtained by heating bisulphide of carbon with bromide of iodine in a sealed tube to a temperature of 150° C for about forty-eight hours, adding afterwards caustic soda to the contents of the tube, and submitting the mixture to distillation, when the tetrabromide of carbon will distil over. Bromoform and bromopicrin, when treated with bromide of iodine, yield the same result. The bromide of iodine can be replaced by antimony terbromide. Tetrabromide of carbon is a white crystalline substance, melting at 91° C., insoluble in water, but readily soluble in ether, hot alcohol, benzol, American oil, bromoform, and chloroform. Sodium amalgam reduces it, first to bromoform, then to methylene dibromide. The authors propose to carry on their investigations of this interesting compound.

Anthropological Society of London, May 3.—Dr. R. S. Charnock, V.P., in the chair. Moore A. Cuffe, LL.D., 9, Camden Crescent, Bath, was elected a Fellow. A paper was read by Major W. Ross King, F.R.G.S., F.S.A.S., on the "Aboriginal Tribes of the Nilgiri Hills," namely, the Todas, Khotas, Erulas, and Kurumbas, especially noticing the former, as being the most singular and important. The author, who was three years among these tribes, described in turn the characteristic features and peculiarities of each, with detailed information as to their very curious social customs, and religious rites and ideas; showing the marked distinction existing in every point between tribes occupying one and the same area, and in constant communication with each other; pointing out the fact that each people retained its own language; and their remarkable isolation from the surrounding enormous population of the plains. The striking similarity between the rites, practices, and monuments of the Todas and those of the ancient Celts of Britain was shown; a passing allusion was made to the evidences of an early western migration as traceable through intervening countries in the existence of similar rites and customs; and the presence on the Nilgiri hills of Druidical circles, cromlechs, kistvaens, and tumuli was described, precisely similar to those so well-known in our own country. While commenting on the analogies thus apparent between the ancient Celts and some of these Hill Tribes, the author took occasion also to remark on their similarities in other respects to the Jews of old, to the Kaffirs, and to the ancient Romans, not as being likely to lead to any theory of origin in those quarters, but as possibly qualifying the reliance to be placed on every point of Celtic resemblance. In conclusion, the author, who illustrated his paper by the exhibition of several drawings, and of some interesting native ornaments, &c., summed up the various theories prevailing as to the probable origin of these tribes, of whose history we are still so ignorant, and recommended the subject to the Society as one worthy of their investigation.

Linnean Society, May 5.—The following foreign members were elected in the place of those who have died during the past year:—Prof. Spencer F. Baird, of Washington; Herr George Ritter von Frauenfeld, of Vienna; Dr. William Lilljeborg, Prof. of Zoology at Upsala; Dr. Charles Naudin, of Collioure, Pyrenees; and Sig. Roberto di Visiani, Prof. of Botany at Padua.—A letter was read from Dr. Ernst, of Caracas, on a peculiar plant belonging to that country known as "incense," a small tree forming a striking feature in the scenery. It was described by Humboldt and De Candolle under different names, its affinities not having been accurately determined. Dr. Ernst has established its right to form a distinct genus, to which he gives the name of *Libanothamnus*.—Dr. Hooker read a communication from Dr. Kirk, vice-consul at Zanzibar, on "Copals." One characteristic by which fossil copal is known from the recent resin, in addition to its greater transparency, is the so-called "goose-skin." Dr. Kirk has ascertained that the fossil copal shows no trace of this goose-skin when first dug out of the earth, but that it makes its appearance only after cleaning and brushing the outer surface. Specimens exhibited of both recent and fossil copal contained imprisoned flowers, leaves, and insects, in a beautiful state of preservation. Captain Grant states that the true copal gum-tree is a climber which climbs to a great height among the forest trees, and finally becomes completely detached from its original root, when the copal exudes from the extremities of these detached roots. Large pieces of the resin fetch a very high price even in that country.

Zoological Society, April 28.—John Gould, F.R.S., V.P., in the chair. The Secretary read some notes on the principal additions to the Society's Menagerie during the month of March, and called particular attention to four Burrowing Owls presented by G. Wilks, Esq., C.M.Z.S., and to a wood-loving antelope (*Cephalophus sylvicultrix*), obtained by purchase.—Mr. J. E. Harting, F.Z.S., exhibited an unusually fine specimen of the Dusky Redshank (*Totanus fuscus*) in summer plumage, recently killed near London.—The Rev. H. B. Tristram exhibited two skins of *Salicaria melanopogon*—a rare European warbler, obtained near Ettawah, north of Agra, being the first recorded occurrence of this species in Central India.—Dr. E. Hamilton communicated an extract from a letter addressed to him by his nephew, Capt. Hamilton, lately commanding detachment at Port Blair, concerning the true locality of the so-called "Andaman Monkey," now in the Society's Gardens, which was stated to have been imported into the Andaman Islands from Burmah. —A letter was read from Dr. John Anderson, F.Z.S., of the Indian Museum, Calcutta, announcing that he had obtained a specimen of the dolphin of the Irrawaddi, which turned out to be a species of the genus *Globiocephalus*.—Mr. St. George Mivart read a memoir on the axial skeleton of the tailed batrachians, containing observations on the development and mode of formation of the spinal column of these animals.—A communication was read from Mr. Gerard Krefft, C.M.Z.S., containing the description of a new and very remarkable animal, allied to *Lepidosiren*, recently discovered in the freshwaters of Queensland. Mr. Krefft considered this animal to be an Amphibian, and referred it to the genus *Ceratodus* of Agassiz, proposing to call it *Ceratodus Forsteri*, after Mr. Wm. Forster, its discoverer.—Mr. R. Swinhoe, F.Z.S., read a paper on the Mammals of Hainan, as observed during his recent visit to that island. The number of species enumerated was 21, amongst which was a hare, believed to be undescribed, and proposed to be called *Lepus hainanus*.—A second communication was read by Mr. Swinhoe, being a list of reptiles and batrachians found in the same island, with notes on their habits. The species had been determined by Dr. Günther. — Mr. D. G. Elliot, F.Z.S., read a paper on some new genera and species of birds belonging to the families *Formicariidæ*, *Pachycephalidæ*, and *Sylviidæ*. These were proposed to be called *Xenorhynchus pachycephaloides* (from New Caledonia), *Clytoctantes alixii* (from Ecuador), and *Calamoherpe subflavescens* (from Dahouria).—Messrs. Sharpe and Dresser read a paper "On some new or little-known points in the economy of the common swallow" *Hirundo rustica*). The authors drew special attention to the changes of plumage through which this species passed during its residence in Southern Africa.—Mr. G. B. Sowerby communicated descriptions of 48 new species of shells from various localities.

CARDIFF

Naturalists' Society, April 5.—A paper was read on "Water in its different forms," by Mr. Vivian. A large number of very interesting objects contained in various descriptions of water were shown under the microscope, among which the most interesting were the contents of two vials, both from a shallow, muddy-looking bog on Splottland Moor, which furnished a puzzle for the members of the Society, and a satisfactory solution of which is still a desideratum. One of these was filled with the yellow gelatinous substance which deposits the famous bog iron, consisting chiefly of a very minutely twisted conferva, which Sir C. Lyell, after Ehrenberg, called *Gallionella*, but which is now more commonly named with Griffith *Didymohelix ferruginea*. Within this yellow substance was an innumerable swarm of bluish-green animalcules (*Stentor polymorphus*), with several specimens of two other kinds of Vorticellineæ—viz., *Urocentrum turbo* and *Cœnomorpha medusula*. This is a very funny living parasol, worth seeing. The other vial, except the yellow stuff, which was eliminated on purpose, had the same trumpeters (*S. polymorphus*), which, wonderful to say, on being corked disappeared, collapsing all at once, and leaving nothing behind but a milky, bluish-green water, which still keeps its colour after several days. We shall wait to see if any living creature will ever come out of it by spontaneous or hemigerminal generation. From another vial a good harvest of phytozoa (*Euglenæ*) was expected, all the water looking deep yellow green; but this water, too, never settled as it does when living *Euglenæ* are collected, a clear proof that here also the animals come to grief—when and how? —that is the question the members of the Cardiff Naturalists' Society wish to have solved by some of our readers. In reference to the contents of a single drop of water, Prof. Gagliardi remarked:—It was in the same gathering that an extremely minute protoplasmic bit of living matter was seen. Under a magnifying power of 500 diameters this floating atom looked like a little comma, scarcely half the size of the *Surirella minutæ* that was living with it. Another unusually large specimen of *Amœba* came out of a gathering in a pond in Cathays; it looked somewhat like a streaming worm. I have no doubt that it was but a stronger variety of the *Amœba princeps*; yet, seeing how steadily it kept to the vernicular form, with very slight changes now and then, I should call it rather *A. vermicularis*.

GLASGOW

Geological Society, April 14.—Professor John Young, President, in the chair.—Mr. James Geikie, Vice-President, read a letter from Mr. Croll, of the Geological Survey of Scotland, referring to a paper contributed by him to the transactions of the Edinburgh Geological Society, on "Ancient River Channels buried under Drift," and on which Mr. John Young had made some remarks at a previous meeting. An animated discussion ensued on the points referred to in the letter.—Mr. D. Bell read a paper entitled "Aspects of Clydesdale during the Glacial Period." He gave a sketch of the succession of events which had been made out from the dawn of the glacial epoch, down to a comparatively recent geological time—beginning with the period of land-ice, and ending with the "last elevation" of the land. As to the period of land-ice, he thought the first point which they had to fix in their minds and try to get some adequate notion of, was the great thickness and mass which the ice attained. He did not know where they could get a better or more impressive idea of this than by ascending Ben Lomond. He described the marks of the ice, the grooved and polished surfaces, that may be traced from the shore at Rowardennan to a great height on Ben Lomond, observing that the ice evidently did not come *down* the mountain, but moved *along* or *across* it. He also referred to similar markings on the neighbouring hills, and the conclusion these all led to was, that the entire hollow in which Loch Lomond now lies was at one time filled from side to side with a mass of ice which only the higher mountains overtopped, and from which Ben Lomond itself only rose as a little rocky islet. Having shown that this was quite in harmony with what had been observed in other parts of the country, among the mountains of Perthshire, Aberdeenshire, and Argyleshire, he said he had no doubt the great depth of Loch Lomond in its upper part, where it is not less than 100 fathoms, was due mainly to the action of the ice, which was there compressed and imprisoned, forcing its way between the hills. In the lower part it got spread out more, so that although it had softer rocks to deal with, it produced comparatively a less effect. He then alluded to similar proofs of glacial action in the neighbouring parts of the Firth of Clyde—at Garelochhead and along the shores of that loch, of Lochlong, Lochgoil, and the Holy Loch—on the hills behind Gourock, Greenock, and Port-Glasgow—on Dumbarton Castle rock—on the flanks of the Kilpatrick hills—on the opposite side of the river near Bishopton, and all over the lower grounds from the Gleniffer and Cathkin braes on the one side, to the Campsie hills on the other. The persistency and uniformity of direction of these markings, alike in the valley and over the neighbouring hills, sufficiently proved the great volume the ice must have attained. He then proceeded to consider the formation of the boulder clay, holding that the lower till or clay was the product of this great sheet of land ice, and that the upper boulder clay was more probably due to sea ice during the period which followed, when the land was submerged to a depth of several hundred feet beneath its present level. He referred to the beds of sand found interspersed throughout the boulder clay, and thought that whether the theory of land or sea ice were adopted, these might be explained without supposing, as some did, that there had been so many distinct "breaks" in the glacial period. He pointed out the narrowness of the basis on which such conclusions rested, only a very few of the borings which had been adduced showing more than one or two beds of sand; and maintained that the one "break" of which we seemed to have evidence, between the first and second depression of the land, was sufficient, if we considered and gave due weight to the gradual advance and retreat of the ice in each case, and the accumulations of water that must have been caused thereby, to account for all the beds of sand that had been described. Coming to the "shell-beds" which had been found at various heights in the Clyde valley, from Airdrie, at 510 feet, down to Paisley, and from that to the present sea margin, he was of opinion that the theory of "unequal elevations," which had been proposed to account for these beds being found at so many different levels, was quite untenable, being a most objectionable and unphilosophical theory in every respect. He believed the true explanation was to be sought, not by supposing the beds to have been strictly *contemporaneous*, or formed at the same level, and afterwards "unequally elevated," but by considering them to have been *successive*, formed at different levels during the gradual sinking or rising of the land, as the depth of the sea, its freedom from ice, and other conditions, became favourable to the various forms of marine life, whose remains are found in the beds referred to.—Mr. John Young then exhibited some specimens of finely-laminated clay from the excavations in the College grounds, pointing out the traces of organisms which they presented, some of which were supposed to be of Annelides, others of Crustacea. Arrangements for the society's excursions during the summer months were afterwards announced, and the proceedings terminated.

PARIS

Academy of Sciences, May 2.—M. Le Verrier communicated a note by M. Aoust on roulettes in general.—The following papers on physical subjects were read :—A memoir by M. Becquerel on the cause of the electrical effects produced by the contact of metals with distilled water, in which the author, after discussing the opinions of previous writers on the subject, and describing his experiments, comes to the conclusion that these effects are due to the reaction of the water upon the gases absorbed by the inoxidisable metals, whilst those furnished by oxidisable metals arise from the presence of a slight coat of oxide upon their surface, which renders them positive relatively to metals not so protected. By M. J. Jamin and M. Cornu, notes in opposition to the results obtained by M. Croullebois with regard to the index of refraction of water; and a a reply by M. Jamin to the recent note by M. Renou on the latent heat of ice. A memoir by M. Lecoq de Boisbaudran on the constitution of luminous spectra, containing a comparison of the spectra of chloride, bromide, and iodide of barium, showing that an augmentation of mean wave-length in some degree proportional to the augmentation of molecular weight, is caused by the substitution of one halogen for another, as well as by the substitution of one metal for another. A continuation of M. P. Desains' researches upon calorific spectra. A note by M. E. Bouchotte, communicated by M. E. Becquerel, on the estimation of the relation existing between the dynamic work expended and the quantity of electricity produced in Holtz's machine, in continuation of a note upon the same subject presented in February last; and a note by M. Limouzin, presented by M. Bussy, relating to a communication by M. Duclaux on the formation of liquid drops, and remarking that the author, more than a year ago, presented to the School of Pharmacy an alcoholometric apparatus constructed upon the principle indicated by M. Duclaux.—A note by M. Lacoine, on the effects produced by the Aurora of the 5th April on the Turkish Telegraphic lines, was presented by M. Leverrier. The author observed a complete stoppage of transmission in the line from Pera to Semlin, the line being traversed by a strong current in the opposite direction, indicating a terrestrial current from north to south.—M. Descloizeaux presented a note on the crystalline form and optical properties of a compound of protochloride of platinum and triethylophosphine analogous to Magnus's salt.—The following strictly chemical papers were also read :—A note by M. Morren to the president on the combustibility of the diamond, and the effects produced upon it by high temperatures. The author stated that when heated by means of common coal, or brought to a white heat in a current of coal gas, diamonds become blackened on the surface, but without change of weight; with pure hydrogen no alteration is produced; with carbonic acid they lose lustre and weight. He added that diamonds burn readily when exposed to the blow-pipe flame of a glass-blower's lamp upon a piece of platinum, and that the whole substance does not burn with equal readiness, so that if the operation is interrupted, the surface of the residue shows numerous small equilaterally triangular faces belonging to minute octahedra.—A note on the solubility of chloride, bromide, and iodide of silver in salts of mercury, by M. H. Debray.—A memoir on a new process for the volumetric determination of copper, by M. F. Weil, communicated by M. Dumas. This process depends on the facts that in presence of an excess of free hydrochloric acid, and at a boiling temperature, the least trace of bichloride of copper gives a distinct greenish yellow tinge to its solution, and that under these circumstances protochloride of tin instantly converts the salts of binoxide of copper into colourless proto-salts. The termination of the reaction is determined by means of bichloride of mercury, which produces the characteristic white precipitate of calomel with the slightest excess of chloride of tin.—A paper on the products of the fermentation of pyrotartaric acid and its homologues, by M. A. Béchamp. The author stated that as succinate of lime by fermentation furnishes butyric acid, with evolution of hydrogen and carbonic acids, its homologue, pyrotartaric acid, might also be expected to produce butyric acid, but that at the close of the operation the apparatus contains only carbonate of lime, whilst the gases evolved are carbonic acid and marsh gas. He also noticed the behaviour of several organic acids when fermented by means of chalk in presence of a small portion of flesh.—A note by the same author on the preparation of pyrotartaric acid. He operates upon anhydrous tartaric acid mixed with pumice, and obtains about 20 per cent. of pyrotartaric acid.—A note by M. F. Pisani on the minerals obtained in the copper mine of Cap Garonne (Var) was communicated by M. Descloiseaux. These minerals are Adamine (of which the author gives analyses), Chalcophyllite, Lettsomite, Brochantite, Olivenite, Mimetese, Azurite, Malachite, and Barytine.—M. Prunières forwarded some specimens of charcoal and carbonised wood, collected in the Lozère from a sedimentary deposit between granite and basalt, at a depth of 40 metres. Some of them bore remarkable notches, "which will have to be studied from another point of view."—M. Duméril communicated some observations by M. E. Moreau, on the structure of the *chorda dorsalis* in *Amphioxus lanceolatus*. Appended to the *chorda dorsalis* in this fish, the author finds neurapophyses and hæmapophyses; he also describes the sustaining pieces of the fins, especially the dorsal, which he regards as representing fin-rays amalgamated with interspinous pieces.—M. Brongriart communicated a memoir by M. A. Gris, containing anatomical and physiological observations on the pith in ligneous plants. The author distinguishes three medullary elements, namely, *active*, *inert*, and *crystalligenous* cells. When the first and third of these are present, he calls the pith *homogeneous medulla*; the first and second constitute a *heterogeneous medulla*. From the presence of starch in the active cells of the pith in large branches and trunks showing from eighteen to twenty-eight circles of growth, the author concludes that the supposed inertia of the medulla is by no means certain. He regards it as an organ of reserve.

BERLIN

Royal Prussian Academy of Sciences, January 6.—The following scientific paper was read :—On the theory of the newest Electrophorous machines and on supernumerary conductor. By M. Riess.

January 17.—Professor W. Peters read a memoir on the Ductus pneumaticus of the lower jaw in the crocodile.

February 10.—Professor W. Peters read a memoir on the African monitors and their geographical distribution, in which he indicated the synonymy and distribution of the following species:—*Monitor niloticus*, Hasselqu.; *M. saurus*, Laur.; *M. albogularis*, Daud.; *M. ocellatus*, Rüpp.; *M. exanthematicus*, Bosc; and *M. griseus*, Daud. He adopts the Cuvierian name for the genus, as it is three years earlier than Merrem's *Varanus*. Prof. Peters also read a contribution to the knowledge of the herpetology of South Africa, including a list of a few species of lizards, snakes, and batrachia, chiefly from Hantam, in the Calvinia district. A new species of gecko, *Chondrodactylus angulifer*, is described and figured by the author; it is the type of a new genus, allied to *Stenodactylus*, but destitute of claws. The author also remarks upon the characters and synonymy of *Agama hispida*, Linn.; *A. atra*, Daud.; *Eremias capensis*, Smith; and *Euprepes vittatus*, Oliv.; and figures two small species of tree frogs, namely, *Arthroleptis Wahlbergii*, Smith; and *Hyperolius tuberilinguis*, Sundevall. He proposes to change the name of his *Hemidactylus variegatus* to *H. picturatus*.—A memoir by M. Kostka, on the determination of the ellipsoidal figure of equilibrium of a homogeneous mass of fluid rotating round a fixed axis, when its density and period of rotation are known, was presented by M. Weierstrass.

February 14.—Professor Dove read a note on the compensation of the cold observed in Europe in January of the present year, by an unusual elevation of the temperature in America.—Professor Ehrenberg made a preliminary communication on the beds of Bacillariæ in the high lands of California, in which he noticed the occurrence of great beds consisting wholly of Diatomaceæ in various parts of the Californian territory.—M. Weierstrass presented a memoir by M. Ketteler on the influence of ponderable molecules upon the dispersion of light, and upon the import of the constants of the dispersion formulæ.

February 17.—The papers read at this meeting were chiefly of historical or antiquarian interest, but they included an important contribution to the history of algebra in Germany, by Prof. Gerhardt, of Eisleben.

February 24.—Prof. A. W. Hofmann read a paper on the preparation of the ethylamines on the large scale. The author finds that the most volatile of the subsidiary products of the manufacture of chloral, if condensed and digested at 212° F. with a strong alcoholic solution of ammonia, furnishes, by a simple subsequent treatment described by him, a considerable proportion of hydrochlorates of the amine bases, which may be isolated by the addition of concentrated solution of soda. Professor Hofmann also read some supplementary remarks upon the products of the desulphurisation of diphenylosulphocarbamide.

German Chemical Society, April 11.—Two papers by L. Carius were communicated. The first describes a new method of preparing dibrominated acetic ether, by the action of bromine on acetic ether. The second announced new syntheses of maleic and phenaconic acids, by the use of disodic acetic ether, $C\ H\ Na_2\ C\ O\ O\ C_2\ H_5$ on bibromoacetic ether, and on bibromosuccinic ether.—Messrs. Schneider and Erlenmeyer have investigated normal iodopropionic acid. Treated with acetate of silver, this acid yields acetoxypropionic acid.—L. Fleury publishes researches on new derivations of allyle, viz.: $C_3\ H_5\ Cl_2\ N\ O_2$, $C_3\ H_5\ I\ Cl_2$ and $C_3\ H_6\ O\ H\ H\ Cl\ O$.—A. Ladenburg has discovered a distannic ethide, $Sn_2\ (C_2\ H_5)_6$. The vapour density serving to establish the formula of this compound was taken by Hofmann's method, the constant temperature being produced by distillation of oil of cloves. Chlorine and iodine separate the molecule producing

$$Sn\ (C_2\ H_5)_3\ Cl,\ \text{or}\ Sn\ (C_2\ H_5)_3\ I.$$

C. Liebermann reported on an easier method patented by himself, in conjunction with Messrs. Graebe and Caro, for preparing artificial alizarine. Instead of brominating anthracene they treat it with sulphuric acid. According to the quantities employed, either one, two, or three atoms of hydrogen are replaced by the group HSO_4. $C_{14}\ H_8\ (SO_3H)_2$ fused with potash yields $C_{14}\ H_8\ (OH)_2$, and this is oxydised into alizarine $C_{14}\ H_6\ (HO)_2\ O_2$. Or they transform anthracene $C_{14}\ H_{10}$ first into anthrachinone $C_{14}\ H_8\ O_2$, and treat this substance with sulphuric acid. The compound $C_{14}\ H_6O_2\ (HSO_4)_2$ may then be transformed by fusion with potash into $C_{14}\ H_6O_2\ (OH)_2$. The compound $C_{14}\ H_5\ O_2\ (HSO_4)_3$ is transformed by this process into purpurine. A process lately patented by Bronner and Gubzkow for preparing alizarine was then severely criticised by Mr. Liebermann; this process, consisting in fusing anthrachinone with potash, yields only a trace of a blue colouring matter, but no alizarine. He intends to return to this subject.—Professor Rammelsberg reported on the action of periodic acid on the oxides of thallium. Protoxide of thallium treated with periodic acid is partly converted into the iodate, and partly into peroxide of thallium. Sesquioxide of thallium, on the contrary, combines with periodic acid.—V. Meyer has continued his researches on the synthesis of organic acids, by treating sulpho-salts with formiates. Sulphonaphthalate of potassium, when fused with formiate of sodium, produces acid sulphite of potassium and naphtalinecarbonate of sodium. Chlorosalylate of potassium treated in the same way, however, yields chloride of potassium and benzoate of sodium.

April 25.—Messrs. Krämer and Pinner have continued their researches on aldehyde by submitting it to the action of chlorine-gas. Conducted in this way, the reaction takes place in a different manner from that described by Wurtz, who, pouring an excess of aldehyde into large vessels filled with chlorine, obtained chloride of acetyle and its compound with aldehyde. Neither of these substances has been obtained by Messrs. Krämer and Pinner. Nor is ordinary chloral obtained by this reaction, the aldehyde being entirely converted into the chloral of the condensed aldehyde, C_4H_6O, known as crotonic aldehyde. Crotonic chloral is a liquid, boiling at 165°, and forming with water, but not with alcohol, a crystalline compound. By oxydation it forms trichlorocrotonic acid. Caustic potash transforms it into the corresponding chloroform $C_3\ H_2Cl_3$ and its derivative $C_3\ H_3\ Cl_2$ (bichlorinated allylene?) boiling at 78°.—C. Martius has studied the combinations of chloral with alcohols. Amylic alcohol forms with it a beautifully crystallised compound. Mercaptans also combine with chloral.—F. Rüdorff communicated a method of determining with great exactness the quantities of pure glacial contained in acetic acid of different degrees of concentration. It is founded on the melting-points of pure acetic acid (16°·7 C.) and its mixtures with water. Commercial glacial acetic acid contains often as much as 10 per cent. of water, and then melts at 10°·3 C., or even 15 per cent., and then melts at—0°·2.

DIARY

THURSDAY, May 12.

Royal Society, at 8.30.—On the Results of the method of investigating the Nervous System, more especially as applied to the elucidation of the Functions of the Pneumogastric and Sympathetic Nerves in Man: Dr. A. Waller (Croonian Lecture).

SCIENTIFIC EDUCATION

THAT the Government of this country is anxious to advance Science education is plainly manifest from what it has already done, in making large annual grants to institutions which it established, and which it maintains as its own. That it does not consider the present arrangements for this purpose as final or sufficient, is clear from the recent appointment of a Royal Commission to inquire into the whole question of Government aid to Science. The movement which resulted in the appointment of this Commission arose, as we have already explained, from a recommendation of the Council of the British Association for a formal inquiry into the existing state of Science education in this country; and the resolution stated: "That no such inquiry will be complete which does not include the action of the State in relation to scientific education, and the effects of that action upon independent educational institutions." Before the Commission meets, it seems desirable that those interested in advancing Science and Education generally, should seriously consider the different position in which Science now stands, as a means of education, to that which it formerly occupied. The time was, and not long ago, when Science was regarded as a thing by itself, having no connection with other branches of education, and useful mainly as a means for rendering men better machinists, better artisans, or discoverers of processes for the advancement of arts and manufactures. Many doubtless hold these opinions at present, and one concludes this to be the case from the very limited view which is expressed by the term "technical education" which is so generally used. Now, if it be desired to promote this view only, and to teach, Science alone, and not as a part of general education Government has established perhaps such schools as might meet the wants of the case, if it can be shown that they fulfil the expectations with which they were founded. But if the higher view, that Science is in its way as important a means of mental training as any other of the branches taught in our schools and universities, then some other method of extending Government assistance for its promotion must be adopted; and it is to this consideration we earnestly hope that inquiries will be directed. Since the first Report of the Science and Art Department, in 1854, sufficient time has been given to show whether the system then originated has answered its purpose. At page 2 of the Report, it is stated that its system will be "in the main self-supporting; while the advantages will be distributed over every part of the United Kingdom; and the assistance received from Parliament be applied for the general good of all." It is generally believed that the system is *not* self-supporting, but that every associate of the School of Mines costs the Government a considerable sum of money. There can be no question that the advantages of the system are very great, directed as it is, in the several branches, by men of the highest possible eminence; but it is urged that they are not to any great extent distributed over the whole country, but mainly collected for the benefit of the technical schools founded by Government, and this tendency to force the official plan of education upon the country is regarded by many connected with other educational establishments as unfair. In fact, there is a threatened crusade against the Government professors.

To such we would remark, that the quantity of Science taught is so small, that it is not wise to attempt in any way to reduce that quantity; but it is certainly to be wished that the Commission should carefully inquire whether this method is one calculated to extend a sound Science education over the whole country, and whether it is possible to judge of a person's fitness to teach, without practical examination in subjects which are eminently practical, and without some guarantee that he has received a sound general education.

The Report further says: "It is essential that the institution should be supported to a considerable extent by the fees of pupils." This, it is urged, is not the case with the London Government school (and still less with the sister College of Science in Dublin), where the fees are not sufficient to pay the working expenses, to say nothing of the salaries of professors, and the scholarships of £50 per annum each, which are held by so large a number of students. At page 9 of the Report, the same important subject is dwelt upon: "My lords concur in the views expressed by the Lords of the Committee of Trade, that every means should be used to render these institutions as much self-supporting as possible, and that, in the plans adopted, that object should always be borne in mind. My lords adopt this view, not only because they feel it incumbent upon them to confine the public expenditure to the lowest limit, but also because they entertain a belief that the utility of such institutions is great in proportion as they are self-supporting." It may not be generally known that large sums have been expended, and further large sums are to be expended, in building and fitting up laboratories, lecture-rooms, &c., at South Kensington. The present time, then, is a very fitting one for an inquiry as to the present wants and resources of the country in relation to the higher science teaching, and the means best calculated to utilize and develope them with due regard to efficiency and economy. If it can be shown that the School of Mines has really done more work than unendowed schools, in proportion to the sums spent upon it, let its sphere of action be enlarged—at South Kensington or elsewhere—and let its usefulness be increased. But it must always be remembered that it professes to give none other than a *special* training: that it in no way supplies the place of universities, colleges, and schools of general education. If, on inquiry, it is found that it has attained the object for which it was established, still that does not touch the recommendation of the Council of the British Association, which includes "the action of the State in relation to scientific education, and the effects of that action upon *independent educational* institutions." It certainly ought to be a subject of serious inquiry, whether or not such colleges as University College, London, which has for forty years trained and sent out into the world some of the most distinguished teachers of Science, which in fact originated the present system of scientific education in union with other branches of education; or King's College, which has in like manner contributed so largely to advance modern education; or Owens College, Manchester, whose students show so well the nature of the education they there receive by the honours and prizes they gain at the London University; or many other flourishing colleges—should have their hands strengthened by Government help. In these institutions a thoroughly sound education, in all branches, is given. They have hitherto depended entirely on voluntary support, but the time has come when larger aid is needed to meet the modern requirements. Scholarships given by Government as incentives to work, and as helps to the many industrious students whose means are limited; stipends to professors, in order that they may obtain teaching assistance of a high character, of which they stand sorely in need, for it is absolutely impossible for them to teach effectively the large classes who place themselves under their guidance; grants for apparatus, and enlarged accommodation for the extension of original research—these are subjects which must occupy the attention of any committee appointed to inquire into the existing state of education. It is now pretty generally admitted by scientific men that no exclusively scientific education can meet our present requirements. On the Continent it is felt that it is only in universities and schools where *all* branches of knowledge are taught, that a really scientific education can be given; and we are glad to find that this opinion has gained ground in this country, together with a conviction that Science studies in their turn render students more apt in the acquisition of other branches of knowledge.

In Germany there is a strong feeling against the establishment of mere technical schools. It is maintained that boys should receive the same training up to a certain stage, and that they should afterwards enter for the special branch they design tofollow. Professor Köchly, of Heidelberg, Professor of Greek, proposes that there should be a thorough but limited instruction in classics, a more extended development of mathematics, a course of instruction in the natural sciences, and systematic instruction in modern languages. Professor Hofmann, who is well known in this country, considers that the best safeguard against the vulgarising of Science, when it is taught with too special a regard to its applications, is to be found in a sound general school training; and he believes that the old gymnasium system is of inestimable value. He asserts that in scores of instances he has seen youths who have come to the chemistry classes in the University of Berlin, with scarcely a knowledge of the meaning of the word chemistry, but who have been well trained in a gymnasium, in a short time completely surpass their fellows, who, in a school of another kind, have acquired considerable knowledge of the elements of chemistry. All the Polytechnic Schools of Germany are rapidly approaching the university type;—the teaching of the *principles* of Science, and not of the applications, is becoming more and more the main object.

LEONARDO DA VINCI AS A BOTANIST

FEW men have better earned the title of universal genius than Da Vinci. An ardent disciple of Nature, disdaining mere superficial knowledge, he went to the root of whatever he took up, and attained an intimate acquaintance especially with everything that bore on his beloved art of painting. And this art was understood by him in its widest sense. Not content with representing the mere outward appearance of Nature or of the human form, he considered it a part of his business as a painter to investigate the laws which produce those appearances or which govern that form in its healthy state. To the long list of his acquirements given in the catalogue of the Louvre collection, as painter, sculptor, architect, engineer, physicist, writer, and musician, may now be added that of botanist. In the first number of a new botanical journal, *Nuovo Giornale Botanico Italiano*, published at Florence, Sig. G. Uzielli has given some interesting extracts from a work by Da Vinci, from which he would appear to have anticipated the discovery of certain botanical laws generally attributed to writers of a later age. These extracts are taken from a section of his great treatise on painting, entitled "On Trees and Vegetation," which, however, is found only in one edition of that work, the Roman. The following are the points on which the originality of his observations deserves especial mention.

1. The laws of Phyllotaxis, or of the arrangement of leaves on the stem. Da Vinci appears to have been the first to observe that the order of growth of the leaves is uniform in the same species; and that their modes of arrangement can be divided into three principal forms—the opposite, the whorled or verticillate, and that usually denominated in text-books the alternate, but which should rather be called the spiral. He also pointed out that in the case of leaves growing in opposite pairs, they are generally arranged in a "decussate" manner, that is, each pair grows at right angles to the pairs immediately above and below it; that when leaves are verticillate, those in each whorl are seldom in a direct line with those in the whorls immediately above and beneath; and that a very common form of the spiral arrangement is that sometimes called "quincuncial," where the cycle is completed by five leaves, the sixth being in a direct line with the sixth above and beneath. Another observation of the great painter's is, that inasmuch as branches grow from buds generated in the axils of leaves, the arrangement of the branches on the trunk necessarily corresponds to that of the leaves on the stem.

In botanical works it is generally stated that Sir Thomas Browne, in his quaint little treatise "The Garden of Cyrus, or the Quincuncial Lozenge," published in 1658 (a work not mentioned in Pritzel's "Thesaurus Litteraturæ Botanicæ"), was the first to describe the spiral disposition of leaves, which was afterwards noticed contemporaneously by Grew and Malpighi. Bonnet,* however, in 1754 followed out the laws of phyllotaxis in a far more exact manner; and the subject has been still further elucidated by Goethe, Schimper, Braun, Steinheil, the brothers L. and E. Bravais, and Martins. To Da Vinci, however, who lived from 1452 to 1519, is clearly due the priority in the discovery of these laws; although, as might be expected, many of his observations show a crudeness and imperfection which have been corrected by more recent writers.

2. The manner in which, from the structure of the trunk of exogenous trees, their age can be determined. This fact, although now familiar to unscientific persons, appears to have been unknown to the ancients; since Theophrastus makes no mention of it, nor does Pliny, who

* Bonnet, Ch., Recherches sur l'usage des feuilles dans les plantes.

cites examples of trees which have been known for a great length of time. The discovery is usually attributed to Malpighi and Grew, who published their works, the former in 1675, the latter in 1682; it was, however, known earlier; for Montaigne, passing through Pisa in 1581, learnt the fact from a jeweller of that town, in terms which recall those used by Leonardo. I transcribe the description of Montaigne:—

"The workman, an ingenious man, and famous for the manufacture of beautiful mathematical instruments, informed me that every tree bears as many circles as the years it has lived, and he showed me this in all the specimens of wood which he had in his shop. And the part which is exposed to the north is firmer, and the rings closer and more dense than the rest. By this means he professes to be able to judge of any piece of wood that is brought to him, both the age of the tree, and in what situation it grew." *

The following are the words of Leonardo:—

"The southern part of the plant shows more vigour and youth than the northern. The rings of the branches of trees show how many years they have lived, and their greater or smaller size whether they were damper or drier. They also show the direction in which they were turned, because they are larger on the north side than the south; and for this reason the centre of the tree is nearer the bark on the south than on the north side."

From this it will be seen that both the observations on the age, and those on the eccentricity of the trunks of trees, attributed hitherto by De Candolle † and others to Malpighi, had been previously made by Leonardo da Vinci.

3. The growth of exogenous stems by the formation of new wood beneath the bark. This he describes in the following sentence:—

"The growth in the size of plants is produced by the sap, which is generated in the month of April between the outside coating (*camisia*) and the wood of the tree. At the same time this outside coating becomes converted into bark, and the bark acquires new crevices of the depth of the ordinary crevices."

It will be seen that, although the painter correctly indicated the portion of the trunk in which the increase takes place, he nevertheless failed to detect the cambium, and the important part which modern researches have shown that it plays in the formation of new wood.

For the above illustrations of the botanical knowledge of Da Vinci, we are mainly indebted to the article already named by Uzielli, who states that he might cite from the "Treatise on Painting" many other observations, generally correct, on the structure and development of plants, on the symmetry of their secondary axes, and on the influence which external agents have upon their growth. Uzielli remarks that it is strange that Venturi does not mention these botanical observations, he having had Leonardo's MSS. for a long time under his hand, not even referring to them in his "Essay on the physico-mathematical works of Leonardo da Vinci," where he claims for the painter the character of a great *savant*, and one of the founders of the experimental method. Amoretti, and all the other illustrators of his life and works, are also silent; and Libri, who wrote after the publication of the Roman edition of the work on Painting, mentions only that Leonardo records in it some botanical observations. Libri was, however, the first to publish the important experiments of Da Vinci relative to the action of poison on plants, discovered in the MSS.* preserved in the Library of the Institute at Paris, in which he also alludes to an ingenious process of drying plants, and reproducing their form easily on paper. Not only these MSS., but those also in the Ambrose Library at Milan, in the British Museum, and at Windsor, and those to be found in some private libraries, would doubtless repay a more careful research than has at present been bestowed upon them; and we would commend the subject to the attention of whoever takes up the thread of the life of Da Vinci, broken by the lamented death of Mr. B. B. Woodward.

Sir Charles Lyell † refers to Leonardo da Vinci as one of the first who applied sound reasoning to the facts of Geology, and who taught the organic origin of fossils. His botanical and geological theories are alike evidence of the spirit in which he applied all the powers of his mind to the observation of the phenomena that surrounded him, and which prompted him to counsel his pupils and readers invariably to have recourse to Nature rather than to the works of man, as their guide and the source of their inspiration.

THE RACES OF INDIA

Memoirs on the History, Folk-lore, and Distribution of the Races of the N.W. Provinces of India. By the late Sir Henry M. Elliot. Edited by J. Beames. (2 vols. Trübner and Co.)

THE above work dates from the time of the old East India Company, bearing ample witness anew to that glorious fertility of genius produced in the full flow of an activity directed seemingly to the development of a purely mercantile policy of the most practical kind—the utilising of a distant continent for the enrichment of a handful of merchants sitting at home at their ease. Such, at least, was the repute enjoyed by the Honourable Court of Directors in their day, and it required no less a change than the transfer of power to as methodical a form of government as that which rules India nowadays to make us see matters in their true light, and bless the memory of John Company. This remark is made, of course, from a scientific point of view, for in every other respect, doubtless, India has at large been the gainer. The Company had served its term, and had to give way to a more central power in the interest of the empire generally. One cannot help contrasting, however, the times that are gone by, when upon the horizon shone such stars of first magnitude in science and literature as Sir Charles Wilkins, Sir William Jones, Gilchrist, Lumsden, Colebrooke, Wilson, Ballantyne, Charles Philip Brown, Roer, Sprenger, with the days that be, when examination tests of the severest kind are in the ascendant, but followed, alas! by no apparent results as far as growth of scientific knowledge is concerned, whatever advantage the service generally may be found to derive from them. Men there are, no doubt, who in the proper spirit, and with no less self-devotion, have continued the work of the past. Such names as Cowell, Nassau Lees, Buehler, Burnell, need only be mentioned to give us hope in the future. But what encouragement have their efforts met with? Unsupported as they are by any government aid, will not such efforts go sadly to waste? We do not mean to insinuate that the State should constitute itself a "Bureau de Surintendance," for the better direction and advancement of science and learning. It may be all very well in its way if the "Ministère de l'Instruction Publique" appoints a "Commission pour l'exploration scientifique de l'Algérie," but in a country of parliamentary government, where most things are left to individual initiative, such a state of things is supposed to be anomalous. A great deal might meanwhile be achieved if the range of knowledge required of an Indian civil servant were narrowed, and if he were plied more amply with knowledge of more immediate use for his future career. Instead of being obliged, as now, to occupy himself *de omnibus rebus et quibusdam aliis*, let his attention be directed to such knowledge as will more immediately concern him, and which, if properly followed up, could not but add greatly to our acquaintance with India. Practically speaking, indeed, such a course seems to be not only advisable, but absolutely necessary. That our authority throughout that region is diminishing according as our military power is less displayed, it would be useless to deny. The greater, consequently, seems the necessity for drawing closer the bonds of union, by employing ourselves more fully with the concerns of the people—not in the carping spirit too often assumed by missionaries, but with the unprejudiced mind of scholars. Occasion has been given to these remarks by the perusal of Sir Henry Elliot's book on Indian races, which, although cast in a form anything but grateful to the ordinary student, teems with most interesting information, not to be met with elsewhere in so condensed a form or backed up by such reliable authority. The work resulted from an order issued by the then Government to the Sudder Board of Revenue, N.W.P., bearing date 14th Dec., 1842, and directing them to compile a glossary of Indian terms in accordance with a comprehensive scheme which comprised not only terms relating to the revenue, but also to matters mythological, and to geographical nomenclature. The plan being but insufficiently carried out by his subordinates, Sir Henry of his own accord took it upon himself, in 1844, to complete the parts submitted to the Government, and reaching down to the letter J, without waiting for the completion of the whole—which, indeed, never seems to have been published —limiting his attention mainly to "tribes, customs, fiscal and agricultural terms." He not only added a great many new headings, but enriched the whole with contributions from his own vast store of historical knowledge, compiled from Mohammedan sources, principally from the "Ayin-i-Akbari," the work of the well-known Minister of the Emperor Akbar, who was the founder of a new era in Indian administration. So far as it goes, it is the nearest approach to an encyclopædia of modern Hindooism we can think of. But to contend that it is anything more than a most convenient book of reference in *practised* and *skilful* hands, would be going beyond the mark. In spite of the more practical arrangement adopted by the present editor, one must have struggled for some time with the difficulties which haphazard transcription of native words into English has put in one's way, in order to know where to find what is sought for, or to identify it if one has come across it by chance. This is the first attempt at a rational way of transcription; but, just because it is the first, it is not yet so consistently carried out as might be wished.

To the editor, for whom we have the greatest respect, and who, by his "Outlines of Indian Philology," has shown how earnestly he goes to work in such matters, we in no wise wish to be unfair. The short space of two months, however, allotted to him for editorial work, was far too short to allow him to think of such a fundamental change as that of digesting the whole of the additional matter, and making it conformable with the rest. To do this would involve immense labour, much more, at all events, than one is called upon to bestow when merely editing another man's work. This leads to another point of the utmost importance for our scientific knowledge of India, the bewildering confusion regarding geographical and other names in their English garb. We have been long in the habit of laughing at philologists pouring showers of abuse on each other on the question whether a certain letter in English transcription ought to have its dot over or under the line. But if we do not adopt a little of their pedantry, we shall see no end of confusion in scientific terminology. Since the days of Gilchrist, in 1802, when he made an appeal to European scholars to adopt a uniform system of transcription, no visible improvement has yet generally taken place. If we should not see the urgent necessity of such a change, he gave us the counterfeit of the Hindustani people spelling and pronouncing *udbikut* for advocate, *usishtun* for assistant, *kotmasool* for court-martial, etc. Nevertheless we go on spelling native names in all manners of ways. No two gazetteers, not even of India proper, agree in their orthography, and we may even say, not one gazetteer is consistent with itself. Look at the index to Allen's map of India, which, after all, is still one of the best. We often find there, under different letters of the alphabet, two places, at only a few minutes' distance from each other, which, if it had not been for the strange disguise in which different surveyors chose to put it from the way in which the name struck their ear, would never have been put down as two, but would at once have led to a more accurate measurement of longitude and latitude. The only way to rectify these errors is now afforded, by comparing those maps in Hindustani and Devanagari character, which are issued from the Surveyor-General's offices at Agra and Allahabad, with our English maps, and rectifying the latter in a systematical manner. We are no better off if we turn to botany and the pharmacopœia. Mr. Watson's index, which was lately compiled with a view of collecting the material, swarms with the most glaring mistakes, which, it is true, will do no harm to the learned in these matters, but it is just for them that such books are *not* published. They are intended for those who, in our busy days, have no leisure to settle all this detail for themselves.

To turn back to our book. Of the hundreds of geographical names contained in it, there are perhaps not ten which one would find in this form on our maps of India. But after more or less experimenting, you would not only find every one of them on the maps, but also in some volume of the latest edition of "Thornton's Gazetteer," and perhaps in the volume in which you least expect to find it. To make the book useful for the general public, therefore, a careful index of all the possible spellings, and reference to the correct one, ought to have been annexed to it. Another English index arranged according to subject matter, such as for instance the one to "Rich's Dictionary of Roman and Greek Antiquities," is still a great desideratum, even after the new distribution in four chapters by Mr. Beames. To give only two or three instances out of many: How is the ordinary reader to know that Bareilly (II., 143) is the same as Barelî (141), and that the latter is the correct form? or that the Jadubans (I., 3) are the same as the Yadbansî's (350), and that Kayat, Kayath, Kayeth, Kaisth and Kaith, as they are spelt in different parts of the book, are the same, namely, Káyastha, and that the name is not composed, as stated, on I., 305, from *kai* and *stittei*? And how, without an alphabetical table of contents, are you to know that contributions to Persian and Slang lexicography are hidden away in pages 178 of the second, and 160 of the first volume?

All this does not, however, detract from the value of the work, which we consider, with the author, as "a basis and starting point" very well worth imitating for all the civilians who go out to India. If every secretary of a Sudder Board of Revenue in India were presented with a copy of this work, and if an injunction were made that either he himself or one of his assistants who is well qualified for the task should from time to time send in reports of what he sees and hears after the pattern of the present book, we might, without outlay to the Government, soon see the book completed to the letter Z, and the same thing done for other presidencies too. But the case occurring, we must beg one thing, that the right man be put in the right place, and that we are to have no more of that gentleman's reports who tries to pass off the names of five great districts and of five great languages for so many "great families." (I. 342). We fancy we see him in our mind's eye sitting down to a task utterly ungenial to him, and after a strenuous effort to huddle it through, only heaping blunder upon blunder. Such discoveries shake our faith in the reliability of his other statements in cases where we have no means to test them by facts established elsewhere, and resting on sufficient authority by themselves.

OUR BOOK SHELF

A Catalogue of British Neuroptera. Compiled by Robert McLachlan, F.L.S. The Ephemeridæ by the Rev. A. E. Eaton, B.A. Published by the Entomological Society of London. 8vo. (London: Longmans. 1870.)

ENTOMOLOGISTS will give a cordial welcome to this first instalment of the catalogue of British insects, the preparation and publication of which has been taken up with such commendable zeal by our Entomological Society. The subjects coming under the domain of entomology are so infinitely numerous, and the literature of the science has increased so enormously of late years, that for any one man to attempt to grapple with it specifically would be almost an act of insanity; and the authorities of the Entomological Society have therefore very wisely entrusted the preparation of different parts of their projected catalogue to those British entomologists who have most successfully studied particular groups. Mr. McLachlan as a zealous student of the Neuroptera is so well known both in this country and on the Continent, that no one else could well have been selected for this part of the task, and he has associated with himself, in the preparation of the list of Ephemeridæ (the well-known May-flies of the angler) a gentleman who, if his published writings are less numerous than those of his colleague, has certainly shown in them that he possesses in a high degree the qualities necessary for the investigation of a rather difficult group of insects.

The order Neuroptera, as understood in this catalogue, possesses the same signification that was originally given to it by Linnæus—that is to say, it embraces, besides the true Neuroptera with a complete metamorphosis, those forms, such as the dragon-flies, May-flies, and some others, which, from their imperfect transformation and certain structural characters, have of late years frequently been placed with the Orthoptera, under the name of "Pseudo-Neuroptera." Under this subordinal or tribual name they figure in this catalogue, and in the present state of our knowledge of the classification of these forms of insects, this is perhaps as good a place for them as any. We have still much to learn as to the affinities of these creatures before any satisfactory arrangement of the families and higher groups can be made, and long and persevering labours, probably in the genealogical direction indicated by Darwinian views, will be necessary before we can clearly understand their true relations, which, however, are the more interesting, as it is undoubtedly in this neighbourhood that we have to seek for the primitive type or types of the whole world of insects. Towards such a happy consummation as the final settlement of so knotty a question as the true classification of the insects comprised under the orders Orthoptera and Neuroptera, such conscientious work as has been put into this catalogue by its authors must greatly contribute.

There is one other point on which we may congratulate the Entomological Society, namely, their adoption of an order of Entomological pariahs, if we may so speak, for the *début* of their catalogue. In Entomology, perhaps more than in any other department of Natural History, fashion rules the day, and the great majority of its votaries devote their whole attention either to Lepidoptera or to Beetles. The fact that one of the most neglected groups of insects has been taken for the commencement of this catalogue of British insects, is, we hope, a sign that the order of publication will continue to be in the inverse ratio of the popularity of the subjects, as we feel convinced that there are many who with any tolerable guidance would be only too glad to acquire some knowledge of the forms of insect-life which lie outside the limits of their present studies.

Ost Afrika: Erinnerungen und Miscellen aus dem abyssinischen Feldzüge. Von Dr. J. Bechtinger. (Wien. 1870.)

DR. BECHTINGER furnishes an account in a light sketchy style of his experience in the Abyssinian campaign as an acting assistant surgeon. The contents of this work are of a very miscellaneous nature, and are not particularly well arranged, comprising scraps of information respecting the diseases of the troops, the treatment adopted for the *Filaria medinensis*, the Yemen ulcer, the character and habits of the Abyssinians, and the incidents of the journey. The descriptions of the scenery are few and short, and there are scarcely any observations of scientific value. We scarcely know whether the book is intended for the general or the professional reader. For the former it contains too much medicine and surgery; for the latter it is almost worthless, and we think the author need not have been so particular in reserving the right of translation and reproduction.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Strange Noises heard at Sea off Grey Town

I AM glad to see that the vexed question of the noise heard from under the sea in various parts of the Atlantic and Pacific has been re-opened by a gentleman so accurate and so little disposed to credulity as Mr. Dennehy. The fact that this noise has been heard at Grey Town only on board the iron steamers, not on board the wooden ones, is striking. Doubtless if any musical vibration was communicated to the water from below, such vibration would be passed on more freely to an iron ship than to a wooden one. But I can bring instances of a noise which seems identical with that heard at Grey Town being heard not only on board wooden ships, but from the shore.

I myself heard it from the shore, in the island of Monos, in the Northern Bocas of Trinidad. I heard it first about midnight, and then again in the morning about sunrise. In both cases the sea was calm. It was not to be explained by wind, surf, or caves. The different descriptions of the Grey Town noise which Mr. Dennehy gives, will each and all of them suit it tolerably. I likened it to a locomotive in the distance rattling as it blows off its steam. The natives told me that the noise was made by a fish, and a specimen of the fish was given me, which is not *Centriscus scolopax*, the snipe-fish, but the trumpet-fish, or *Fistularia*. I no more believe that it can make the noise than Mr. Dennehy believes (and he is quite right) that the *Centriscus* can make it.

This noise is said to be frequently heard at the Bocas, and at Point à Pierre, some twenty-five miles south; also outside the Gulf along the Spanish main as far as Barcelona. It was heard at Chagreasancas (just inside the Bocas) by M. Joseph, author of a clever little account of Trinidad, on board a schooner which was, of course, a wooden one, at anchor. "Immediately under the vessel," he says, "I heard a deep and not unpleasing sound, similar to those one might imagine to proceed from a thousand Æolian harps; this ceased, and deep and varying notes succeeded; these gradually swelled into an uninterrupted stream of singular sounds, like the booming of a number of Chinese gongs under water; to these sounds succeeded notes that had a faint resemblance to a wild chorus of a hundred human voices singing out of time in deep bass."

He had, he says, three specimens of the trumpet-fish, said to make the noise, either by "fastening the trumpet to the bottom of a vessel or a rock," or without adhering to any object. The whip-like appendage to the tail, which he describes, marks his specimens at once as *Fistularias*.

Meanwhile, it is but fair to say that Mr. W. W. Spicer, a few weeks since, called attention to this "Sirene," or musical fish, in Hardwicke's *Science Gossip*, commenting on an account of its being heard commonly in the Bay of Pailon, Esmeralda, on the Pacific shore, in latitude 4° north. I replied shortly in the same excellent magazine, and offered to write further, a promise which I should have redeemed, had not I understood that my learned friend Dr. Günther, in the meanwhile, was about to write on the matter himself, telling far more than I could have told.

Another instance of this sound being heard on board a wooden ship (and this time again in the Pacific) is given (in p. 304 of Mr. Griffith and Colonel Hamilton Smith's edition of Cuvier's Fishes, on no less an authority than that of Humboldt who (say the editors and authors of the Appendix) did not suspect the cause. "On the 20th of February, 1803, toward seven in the evening, the whole crew were astounded by an extraordinary noise, which resembled that of drums beating in the air. It was at first attributed to the breakers. Speedily it was heard in the vessel, and especially toward the poop. It was like a boiling, the noise of the air which escapes from fluid in a state of ebullition. They then began to fear that there was some leak in the vessel. It was heard unceasingly in all parts of the vessel, and finally, about nine o'clock, it ceased altogether. From the narration (says Cuvier) which we have extracted, and from what so many observers have reported touching various Sciænoids, we may believe that it was a troop of some of these species which occasioned the noise in question."

For there is, without doubt, a great deal of evidence to show that certain Sciænoids make some noise of this kind. The *Umbrinas*, or "maigres" of the Mediterranean and Atlantic are said to be audible at a depth of twenty fathoms, and to guide the fishermen to their whereabouts by their drumming. The fishermen of Rochelle are said to give the noise a peculiar term, "seiller," to hiss; and say that the males alone make it in spawning time; and that it is possible, by imitating it, to take them without bait. The "weak-fish" of New York, (*Labrus squetaquee* of Dr. Mitchell) is said to make a drumming noise. But the best known "drum-fishes" are of the genus *Pogonias*, distinguished from *Umbrina* by numerous barbules under the lower jaw, instead of a single one at the symphysis. M. Cuvier names them *Pogonias fusca*, and mentions that "it emits a sound still more remarkable than that of the other Sciænoids, and has been compared to the noise of several drums." The author of the Appendix states that these "drum-fish" swim in troops in the shallow bays of Long Island; and according to Schœpf (who calls them *Labrus chromis*) assemble round the keels of ships at anchor, and then their noise is most sensible and continuous. Dr. Mitchell, however, only speaks of their drumming when taken out of the water. Species of the same genus, if not identical, are found as far south as the coast of Brazil; and it is to them, probably, that that noise is to be attributed which made the old Spanish discoverers report that at certain seasons the nymphs and Tritons assembled in the Gulf of Paria, and made the "Golfo Triste glad with nightly music."

How this noise is produced, if the theory be true, I cannot say. Early naturalists looked, naturally, towards the large and strong swimming bladders, observing, at the same time, that these have no communication with the intestinal canal, nor with the exterior generally.

It only remains to me now to quote the opinion of Dr. Günther, to whose courtesy I owe the sight both of the fish and of its pharyngeal and vomerine teeth. He thinks, with later naturalists, that the noise might be made simply by large shoals of "drums" grinding these teeth together, whether in masticating the crabs, &c., on which they feed, or for mere sport.

I would, therefore, request Mr. Dennehy, or any officers of the Royal Mail steamers who may visit Grey Town, to try if they cannot catch a *Pogonias* or two. Of course, finding them there will not prove that they make the noise, but it will be at least one fresh link in a long chain of evidence.

And so I leave the matter, apologising for having quoted from no later authority than the Cuvier of 1834, which is the only book accessible to me; and for myself, "holding it for rashness hastily to avouch or deny aught amid such fertility of Nature's wonders."

C. KINGSLEY

[Mr. Kingsley will find references to all the various authors who have written on Sciænoids generally, and "Drum Fishes" especially, in Dr. Günther's "Catalogue of Fishes," vol. ii., p. 270 *et seq.*]—ED.

WITH reference to the communication published in last week's NATURE, on "Strange Noises heard at Sea off Grey Town," it does not appear necessary to refer these noises to any occult galvanic agency, or magnetic influence in connection with iron ships, although at first sight, and more especially as there is much ferruginous sand in the vicinity, and as the sounds are heard only in iron ships, and not in wood-built, copper-bottomed vessels, there seems ground for such an idea. The solution I would venture to offer is that these noises proceed from "musical fish" or shells.

Musical sounds proceeding from under water, agreeing in character with those described by Mr. Dennehy, appear to be known on the western coast of India and on the coast of Chili. A very interesting account of these musical sounds will be found in Sir Emerson Tennent's work on Ceylon, from the author's own experiences at Batticaloa in that island. His impressions as to the gentleness and harmony of the sounds are as vividly described as those of your correspondent from the Royal Mail Ship *Shannon*: and although Sir E. Tennent throws no light on the remarkable periodicity of the phenomenon, yet he gleaned by his inquiries that the sounds were heard at night, and most distinctly when the moon was nearest the full. Your readers will find the details at p. 468 *et seq.*, 2nd vol., Edition of 1859.

The iron ship is, in all probability, from the thinness of the plates, a far better musical sounding-board than the thick-bottomed wooden ships, and here we may have the reason of the delicate sounds not being heard in the latter class of vessel.

It has always appeared to me that this particular locality of the River San Juan and its embouchure at Grey Town, offers a rare field for research to the naturalist and speculative geologist.

In my early service—1834—I was engaged in the Admiralty nautical survey of the then harbour at the entrance of the River San Juan, subsequently well known as Grey Town. At that time it afforded a secure and fairly spacious anchorage for a few vessels of even 24ft. water (sheltered by a sandy peninsula) with a wide and clear approach.

Between 1834 and 1839 the end of this sandy peninsula, Arenas Point, advanced considerably across the entrance towards the opposite shore, in a depth of five-and-a-half fathoms. In 1859, the point had reached to within a cable's length of the main land, or over 6000ft. in advance of its position twenty-five years previously, in depths varying from 33ft. to 18ft., practically closing the port except to a small description of vessel.

These great geological changes—if they may be so called —in so short a period of time, destroying as they have done a useful port, are an interesting, and, so far as I know, an unique fact; but the point to which I would wish to refer in connection with the musical fish (?) is the vast amount of animal life observed at the time of the original survey alluded to. The port literally swarmed with fish, but we could not venture to haul the seine more than twice, from the circumstance that large alligators came up in it, to the consternation of the fishermen and the destruction of the nets. Sharks of huge size rendered precaution from falling overboard a matter of some moment, as an unfortunate pet monkey discovered by being instantly seized. This abundance of life, proof of good feeding-ground, may have some connection with a well-developed species of musical fish; but this speculation must be left for your naturalist readers. F. J. EVANS

PERHAPS your correspondent, Charles Dennehy, M.R.C.S.I., R.M.S. *Shannon*, may find an interpretation of the nocturnal musical phenomenon (mentioned in NATURE, No. 28) experienced by iron ships when at anchor in seven or eight fathoms, with a bottom consisting of *a heavy, dark sand and mud containing much vegetable matter*, in the following natural system of gas-escape. In examining certain pools of water in the East, notorious for their poisonous qualities at certain seasons of the year, I was aware of intermittent risings of vast quantities of bubbles. The waters rested on vegetable deposits; if these were stirred up, large globules rose with considerable force, and I came to the conclusion that these air risings were due to the escape of gases from the decomposing vegetable matter. If any metallic body had met these bubbles as they rose, some sound would have been produced, the nature of it depending on various causes. The reason of the sound being heard on board ship between twelve and two, and not between two and four, is owing to a very simple, but beautiful rule of law: as the gases are at all times collecting, we might suppose that they would be at all times escaping, but as the surface of the bottom is of an elastic nature, the water pressure imprisons the gas as if it were within a valve; but when the force of the gas overpowers the water pressure, there is a bubbling escape till the collected gases are expended, and thus I account for the sounds continuing "*about two hours, with but one or two very short intervals*." It is by no means improbable that the musical performance occurs more than once in the twenty-four hours, though the ordinary noises of shipboard prevent its being audible. I believe there is no other way of accounting for this incident; but the test I would propose is to stir up the bottom on a calm day with considerable force; if large quantities of air-bubbles arise, the sailors may rest satisfied that the concert is not given by ghost, mermaid, or siren, but simply by a continued contact of myriads of gas globules against the ship's bottom. The stirring up will not necessarily cause the sound, as the bubbles may be diverted by undercurrents. H. P. MALET

The Sources of the Nile

IN the fifth (May) number of the *Geographische Mittheilungen*, I publish an article and two maps on "Livingstone's Travels and Discoveries from 1840 to May 1869," one of the maps being carefully compiled from the original Portuguese publications of the Portuguese journeys since 1798—viz., those of Dr. Fr. José de Lacerda e Almeida, the Pombeiros Joao Baptista and Pedro, Major Monteiro, and others, showing all that is at present known of those regions. Both maps and text keep aloof from theories and speculations as to the connections of rivers and lakes discovered by Livingstone and the Portuguese with the Nile.

Of the two points at issue, the one as to the connection of the Lake Tanganyika with Albert Nyanza, Livingstone says:—"Tanganyika and Nyige Chowambe (Baker's?) are one water;" but gives no proof of it, having evidently derived his information from hearsay. The most reliable information on this point seems to me that supplied by Burton (Journal R. G. S., vol. 29, p. 254):—"At the head (northern end) of the Tanganyika lies the land of Uzige," in which land, "according to the guides, six rivers fall into the Tanganyika in due order from the east—the Kuryamavenge, the Molongwe, the Kavinvira, the Kariba, the Kibaiba, and westernmost, the Rusizi or Lusizi. The latter is the main drain of the northern country, and the best authorities, that is to say those nearest the spot, unanimously assert that it is an influent."

Regarding the Kassabi, the upper course of which was explored by Livingstone, Ladislaus Magyar, and Rodriguez Graça, it appears to me that the most reliable information we possess of its lower course is that supplied by Livingstone, as collected by him when at Cabango in 1855 (Livingstone's Missionary Travels in South Africa, pp. 457 and 458):—"Several of the native traders here having visited the country of Luba, lying far to the north of this, and there being some visitors also from the town of Mai, which is situated far down the Kasai, I picked up some information respecting those distant parts. In going to the town of Mai, the traders crossed only two large rivers, the Laojima and Ohihombo. The Kasai flows a little to the east of the town of Mai, and near it there is a large waterfall. They describe the Kasai as being there of very great size, and that it thence bends round to the west. On asking an old man, who was about to return to Mai, to imagine himself standing at his home, and point to the confluence of the Guango and Kasai, he immediately turned, and pointing to the westward, said, 'When we travel five days (thirty-five or forty miles) in that direction, we come to it.' He stated also that the Kasai received another river, named the Lubilash. There is but one opinion among the Bovonda respecting the Kasai and Guango. They invariably describe the Kasai as receiving the Guango, and beyond the confluence assuming the name of Zairé or Zerézeré. And the Kasai, even previous to the junction, is much larger than the Guango, from the numerous branches it receives. Besides those we have already crossed, there is the Chihombo, at Cabango, and forty-two miles beyond this, eastward, runs the Kasai itself; fourteen miles beyond that the Kaunguesi; then, forty-two miles further east flows the Lolua; besides numbers of little streams, all of which contribute to swell the Kasai. The town of Mai is pointed out as to the N.N.W. of Cabango, and thirty-two days or 224 miles distant, or about lat. S. 5° 45'. It is evident, from all the information I could collect both here and elsewhere, that the drainage of Londa falls to the north and then runs westward. The countries of Luba and Mai are evidently lower than this, and yet this is of no great altitude, probably not much more than 3,500 feet above the level of the sea. Having here received pretty certain information on a point in which I felt much interest, namely, that the Kasai is not navigable from the coast, owing to the large waterfall near the town of Mai * * *" AUGUSTUS PETERMANN

Gotha, May 2

Scandinavian Skulls

IN his recent lecture on the "Forefathers of the English People," Professor Huxley says, "It is a very remarkable circumstance that the skulls of the existing Scandinavians . . . are *long*;" and he contrasts their dolicephalous type with the round forms of South German, Swiss, and ancient Belgic heads. He also thinks it likely that the Scandinavian invasions of England brought a "longer form of head" into fashion amongst us. The same doctrine is taught by Sir Charles Lyell, in his "Antiquity of Man," and even in the sixth edition of his "Elements of Geology," he says that the Scandinavian skulls of the dolmen period are brachycephalous, or round; those of the iron age being dolicephalous, or long.

Such notions were once current in Sweden and Denmark, but they are now exploded. Originally deductions from history, they rest on no basis of observed fact, and archæology plainly contradicts them. Thirty or forty years ago, Scandinavian *savants* believed, on historical and philosophical grounds, that Lapps and Finns were the earliest inhabitants of the Baltic North, that after them came a Celtic, and finally a Gothic invasion. As Scandinavian archæology grew into a science, and the remains discovered were seen to fall into a stone, a bronze, and an iron series, the three groups collected were, in obedience to the previously existing historic theory, respectively labelled Finnish, Celtic, and Scandinavian. Now, it happened that the first *two* obviously prehistoric skulls found in Scandinavia were of the round type, on which circumstance a learned person (Retzius, if I remember rightly), jumped—in characteristic nineteenth-century style—to the conclusion that the *whole dolmen race* was round-skulled. Never was a more monstrous generalisation built on a miserable collection of two particulars. There are known to exist in museums about 80 skulls attributed to dolmen men, some of which are, perhaps, of questionable origin. These crania are of every conceivable type, being, in fact, identical with modern churchyard skulls. No one pretends that their form is short, or Celtic, or Finnic; and some authorities allege that they are mostly long. These facts are notorious enough in the North. They were ventilated at the late Copenhagen Archæological Congress, and it was not denied on any side that the stone age skulls would suit modern Danes and Swedes. The short skulled stone man is in fact gone the way of the basilisk and the Vital Force, and it is time for him to take his departure from the authoritative scientific teaching of Great Britain.

Professor Huxley appears to believe that the Northern Bronze, or Iron Man, was long skulled. Although this view is quite unsupported by facts, it may be backed by an argument from the domain of the Higher Criticism. In the Museum of Rosenberg are casts of the so-called Gold Horns, the originals of which precious runic articles were stolen nearly 70 years ago. One of these horns bears the inscription—"Ek hleva gastim holtingam horna Favido," which every runologist can read easily enough. But no two runologists agree even approximately in their versions, so that no date can be given to the horns from inferences built on the style of the inscription. However, Professor Steenstrup has pointed out that some figures of men engraved on the horns have heads of a longish appearance, which conclusive fact tells in favour of Professor Huxley's dolicephalous doctrine, although some learned Danes consider that the skulls represented on the horns were obviously Oriental and not Scandinavian.

According to the highest Copenhagen authorities, there is no ground whatever for the assertion that modern Scandinavian skulls are of the long type. It is equally incorrect to say that Scandinavians are fair-haired and blue-eyed

Copenhagen G. STRACHEY

The Anglo-Saxon Conquest

IN an interesting paper, quoted at p. 661 of NATURE, Prof. Rolleston dwells upon the proportion of short-lived male skeletons, found in Anglo-Saxon interments, as contrasted with the older character of the Romano-British interments, deducing therefrom a conclusion as to their respective longevity. The writer appears to have forgotten that the youth of Romano-Britain had for many generations been forcibly expatriated—drafted abroad to feed the armies of Imperial Rome. A. HALL

Analogy of Colour and Music

MR. W. S. OKELY accuses me of having criticised his letter "far too hastily," and writes that he does *not* compare the *diameters* of Newton's rings with one another, but their *cubes*. On referring to his letter in NATURE for Feb. 10, I read as follows:—"Professor Zannotti, of Naples, gives for the *diameters* of the rings from red to red, the cube-roots of the numbers 1, $\frac{8}{9}$, $\frac{5}{6}$, $\frac{3}{4}$, $\frac{2}{3}$, $\frac{3}{5}$, $\frac{9}{16}$, $\frac{1}{2}$. The intervals between these, taken successively, are $\frac{9}{8}$, $\frac{16}{15}$, $\frac{10}{9}$, $\frac{9}{8}$, $\frac{10}{9}$, $\frac{16}{15}$, $\frac{9}{8}$." Your readers can now judge whether my failure to apprehend Mr. Okely's measures was due to my undue haste or his obscurity of expression. When Mr. Okely speaks of my "doubting the accuracy" of Professor Zannotti and M. Biot, he is drawing entirely on his own imagination; what I *did* doubt was the value of the deductions drawn by Mr. Okely from their figures. I *now* doubt his power of distinguishing between external facts and those evolved from his own moral consciousness.

Trin. Coll. Cambridge, May 4 SEDLEY TAYLOR

Colour of the Sky

YOUR correspondent "H. A. N." will find some interesting remarks on the blueness of the sky in Professor Tyndall's "Glaciers of the Alps" (p. 257, &c.), and one or two additional notes in my "Alpine Regions," p. 150. With regard to the colour of the sky at great heights, I can inform him that in fine weather the blue becomes deeper as one ascends, as has been noticed by many persons accustomed to mountain climbing. The most striking instance that I have seen was during an ascent of Monte Rosa, 15,217 feet. On this occasion the colour was so deep as almost to approach a black, as deep as or deeper than the richest hues of *Gentiana acaulis*. This intensity of colour was only very conspicuous during the last few hundred feet of the ascent; and in expeditions to mountains of nearly the same height I have not often seen it approached, never surpassed. Mr. Hincliff in his "Summer Months among the Alps," p. 111, calls attention to the same phenomenon on Monte Rosa, and very appositely quotes Shelley:

> The sun's unclouded orb
> Rolled through the black concave.

T. G. BONNEY

The Royal Society

I CANNOT but think that the list of candidates recommended by the Council for election into the Royal Society published in your last number will be read by the outside world with considerable surprise. I look in vain in it for the names of two men, at least, of world-wide reputation, and well known as no mere *dilettanti* in their respective sciences, who were among the candidates, while the names of others are found there, which are on everybody's lips with the thought, What have they done to merit the scientific distinction which is looked on by every lover of science as almost an opening of the gates of paradise? Is it possible for us outsiders to learn anything of the considerations which govern the election? NOT AN F.R.S.

The Origin of Species and of Languages

ALTHOUGH the origin of languages is due, doubtless, to the gradual variation, selection, and combination of a few primary sounds, partly emotional, partly imitative; yet the process differs essentially from the Darwinian in one all-important respect—that it is carried on by the countless efforts of *rational* beings. No irrational animal, though capable of uttering emotional sounds that are quite intelligible to its fellows, and though in some instances capable of imitating both natural and articulate sounds in a remarkable degree, has ever formed a language, simply because it wants reason. Therefore the analogy, in so far as it really holds, seems to tell against the Darwinian theory, in as far as that ascribes the origin of species to *reasonless* variation and selection.

To me this seems a most important consideration. But I cannot trespass further on your space.

Stirling WILLIAM TAYLOR

TAUNTON COLLEGE SCHOOL

THE educational scheme which occupied much of the late Lord Taunton's attention during the last years of his life, but of which he only saw the beginning, has now come into practical working. Under ordinary circumstances the development of an ancient Grammar School into a modern Public School would merely pass as one of the now frequent symptoms of advance in English higher education. Thus the removal of Bishop Fox's foundation (A.D. 1522) to a fine range of buildings outside Taunton, would hardly demand notice here. Our readers, however, whose attention was taken by Mr. Tuckwell's paper on Science Teaching in Schools (NATURE, No. 1), will see that the application of his system on a much enlarged scale is likely to affect considerably the position of science in the West of England. While calling public attention to the admirable educational arrangements of this particular school, we wish to remark on science teaching in schools in general, with regard to two points which we observe to be often misconceived by the very teachers and parents whom they especially concern.

First, as to the amount of other work displaced by the introduction of Physical Science as one of the regular parts of the school course. In the mediæval system, still not extinct, the forty-two working hours per week were given almost exclusively to classics. In any really good school these hours have now to hold at least an equal average of classical learning, beside English and French, sometimes German, as well as mathematics, geography, history, &c. The problem of doing much in the same time as used to be spent in doing little, is, to a great extent, solved by mere improvement of method. The old classical teaching was so clumsy and repulsive, that its results, so far as it suits the new system to strive for them, may be obtained in one quarter to one half of the time formerly allowed. In addition to this, there are some products of the old system which the new must almost perforce abandon. Latin verses demanded a minimum of ten hours per week out of a total of forty-two working hours. Now, it cannot be too clearly impressed on the minds of persons interested in education, that the time required for giving a well-grounded acquaintance with elementary science is four hours per week.

Second, it is often thought by parents that science, while valuable to boys about to pass certain examinations, or to enter certain professions, is merely of the nature of an "extra accomplishment," not affecting the rest of the educational course. Nothing can be less true. It would be nearer the fact to say that the especial importance of science-teaching in schools, is in its serving beyond any other known means to open children's minds, to stimulate their reasoning powers ; not to teach dull formulas, learnt by a *memoria technica*, but to start boys and girls on a course of realising and comprehending life and nature. This statement (as is right with a statement concerning physical science) is one to be tested by direct experiment. Take a class of children brought up to learn Latin and Greek, Geography and History, and Mathematics, but on whose minds the idea has scarcely dawned that these matters concern real places and people and things. Unfortunately, nothing is easier than to find such classes, grinding on, year after year, in the fond belief that, because school work is dull and toilsome, it must be profitable. Now, let an intelligent teacher give these unlucky children an elementary science lesson : for instance, how it is that bodies fall, what causes summer and winter, how the thermometer does its work. In half an hour's time it will be seen in the very faces of the children, that the lesson, independently of its value for itself, has actually repaid the time spent on it, in the newly-aroused attention and reflection it has gained for other studies. It is no exaggeration to say that four hours of really live teaching in science fully pays for itself in the improved quality of the rest of the week. For this cause it is that science is not made optional at the Taunton School. It is taught simply, and with inexpensive apparatus; but every boy is required to collect his own specimens, to perform his own experiments, and to show at every step that he knows what he is doing.

It seems to us that in some few of the really enlightened public schools, such as that we are now writing of, nearly the highest ideal of training has been attained to, compatible with the present habits of English life. When boys, fresh from an intelligent governess at home, or from a ladies' preparatory school of the best sort, go through the full school course from 11 to 17, working steadily on without flagging and without strain or hurry, at an education which they understand to be the direct and purposeful preparation for active business or professional life, such boys start with success in their hands. It is the result of such education that the professional "crammer" tries to simulate when he endeavours to make 12 months' over-work, ruinous to body and mind, produce at the examiners' table the semblance of seven years of steady mental growth. The examiner knows better, and the real business of after-life shows before many years are out the difference between cram and real education.

THE SCIENCE OF EXPLOSIVES AS APPLIED TO WARLIKE PURPOSES

II.—RECENT IMPROVEMENTS IN THE MANIPULATION AND FIRING OF EXPLOSIVE CHARGES

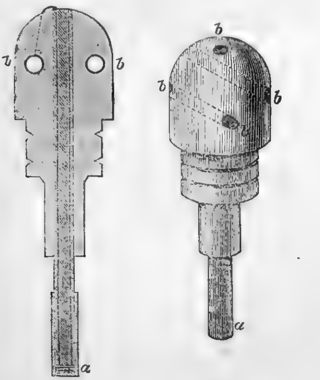
AS we have already shown, the employment of explosive charges is a branch of warfare to which the attention of military engineers has been directed for some time past. For warlike purposes, as also for the destruction of wrecks or other submarine obstructions, explosions have been frequently applied in earlier times, but the methods resorted to for igniting them were, as may be supposed, exceedingly crude and primitive ; sometimes a clock-work arrangement was used, sometimes an encased slow match, and, occasionally, explosion was brought about by means of heated shot dropped down a metal tube. As would naturally be inferred, the difficulties and the frequently unsatisfactory results attendant on explosions of this kind rendered their profitable application a matter of considerable doubt, and few successful records of their employment are to be found.

During the past few years our knowledge of the science of explosives has been considerably enlarged. Not only has the subject of igniting charges been studied to such an extent as to form, at the present time, almost a science of itself, but the nature of the combustible material has likewise been changed and improved ; and military and naval engineers have thus been placed in possession of a source of power, of which we hardly know whether to admire more its unlimitable force, or its wonderful plasticity.

The first practical application of electricity to igniting gunpowder, although such a proceeding was considered possible both by Franklin and Priestley, was not made until about thirty years ago, when some French military engineers employed a voltaic battery as a means of explosion. The method used by these officers was the simple and well-known one of connecting the two conducting wires by a thin platinum thread, the resistance offered to the passage of the electric current by that metal causing its temperature to be raised to a degree sufficient to ignite any charge of gunpowder in contact with it. This manner of applying the electric current as a source of heat is both simple and practical, but it frequently lacks, besides other qualities, the essential virtues of certainty and instantaneity, and it was for this reason that further investigations of the subject have been from time to time carried on. Among others, Colonel Verdu, a Spanish officer, made some progress in the matter, and was successful by the aid of a Ruhmkorff induction coil in exploding several charges simultaneously. This officer's first attempt was to fire the gunpowder by simply allowing a powerful spark to pass from one pole to the other of two wires imbedded in the charge ; he found, however, that ignition in this manner was by no means to be relied upon, but that by covering the poles with fulminate of mercury, a substance more readily inflamed, the desired result was readily secured. Some successful results were also obtained about the same time by employing a particular electric fuze, known as Statham's.

A few years later, in 1856, Sir Charles Wheatstone and Mr. Abel devoted considerable time to the prosecution of further researches, and each of these gentlemen contributed an important discovery, which had the effect of perfecting this interesting application, and rendering it a practical and valuable aid to military science. The employment of electricity induced by magnetism was suggested by Sir Charles, who, after some preliminary experiments, constructed an exploding instrument in which the electricity was created by the rapidly revolving armatures of a compound magnet; and the successful application of this machine was effected through the agency of an electric fuze, devised by Mr. Abel, and of which a sketch is here given.

The chief condition to be fulfilled in the construction of an electric fuze was the preparation of a compound which should combine high conducting power with great susceptibility to ignition, and this, after patient and renewed investigation, was ultimately accomplished. A mixture of subphosphide of copper and subsulphide of copper with chlorate of potash afforded a composition which was exploded with perfect ease and certainty by a current from a small magneto-electric machine, a larger apparatus of the same kind being capable of igniting twenty or thirty of these fuzes almost instantaneously. The means at command afforded, under certain circumstances, by a Wheatstone Exploder and the Abel fuzes, can scarcely be valued too highly, and it has been stated that the Governor of Malta, if provided with these valuable aids, might by himself conduct the defence of Valetta Harbour from his own drawing-room window. This may indeed be a vainglorious boast, but as a matter of hard fact we may mention that the Time Guns at Newcastle, Edinburgh, and other northern towns, have been ignited for some years past from Greenwich Observatory, through many hundred miles of wire, by an Abel fuze with infallible precision and certainty.



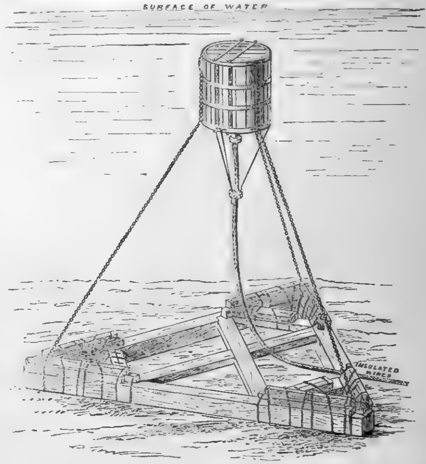
Section *Perspective view*

ABEL FUZE

a, cap of composition, into which the two poles of the wires are fixed.
bb, metal eyes for connecting the insulated wires with the fuze.

Since the date of these improvements, much further experience has been gained in regard to the most suitable description of apparatus to serve as exploders, frictional and dynamo-electric machines, as also miniature voltaic batteries taking the place of the Wheatstone instrument; the electric fuze has however stood its ground in spite of many rivals, and still continues to be used for the ignition of explosive charges, including torpedoes and submarine mines.

As mentioned in the first part of this paper, the Americans employed electricity for firing some of their torpedoes, but they are by no means the only nation who has done so. In the Austro-French war, when the capture of Venice was feared by the Austrians, a very ingenious system of electric torpedo defence was organised at that seaport by a distinguished officer of Engineers, Colonel von Ebner. A camera obscura was erected in proximity to the harbour in such a manner that the horizontal table of the instrument reflected the whole area of the channel. Large wooden cases, each containing 400 pounds of gun-cotton, were lowered at certain fixed distances into the water, and as these disappeared one by one, a small row-boat described at the time a circle round the spot to indicate the extreme confines of the distance at which the torpedo would prove effective; an observer was stationed in the camera as these operations were going on, carefully watching their reflection in the instrument, and as each torpedo disappeared into the water, he marked with a pencil its precise locality on the white table, tracing also the ring formed by the row-boat. Thus a series of circles was formed in the camera, each of which was marked with a distinctive number, and in this way a miniature, but exceedingly correct, plan of the obstructions in the harbours was prepared; the wires in connection with the torpedoes were afterwards led up into the camera obscura and furnished with numbers to correspond with the circles. By means of this arrangement a sentinel stationed in the apparatus might at once explode any one of the torpedoes, as soon as he observed the reflection of an enemy's ship pass within the limits of the circles marked upon the table. The channel itself was quite clear of any suspicious buoys and beacons, and appeared to the enemy wholly free from obstruction.



GUN-COTTON ELECTRIC TORPEDOES CONSTRUCTED AT VENICE IN 1859

In our own country the question of torpedo warfare has for some years past been the subject of study and investigation, and a system has lately been elaborated which owes its origin mainly to Mr. Abel, the scientific referee of the War Department, and which is at once so simple and practical that it cannot fail, in the future, to form a new and interesting branch of war science.

Mechanical torpedoes present so many serious defects (as for instance their liability to get out of order, the risk incurred in mooring them, and the danger they involve, when once sunk, to friend as to foe), that all idea of their employment was at once abandoned by our authorities, and the investigations confined to the devising of efficient electric torpedoes. Of these many descriptions have been designed, but the two kinds held most in favour are the self-exploding instruments, and those which are capable of sending a signal when touched by a passing vessel to indicate the proper time of effecting their ignition from the shore.

The self-acting electric torpedo is of very simple construction, the following being a general outline of one form of it. An Abel fuze is fixed in the torpedo, one pole of which is connected to a constant battery on shore by means of an insulated wire, while the other pole is in communication with an insulated metal plate fixed inside a pivot in the upper part of the machine. Upon this pivot swings a moveable hood, or cage, and the latter, though not affected by the motion of waves, will, upon being struck by a passing vessel, swerve round and come into metallic contact with the insulated plate above mentioned, thus completing the electric circuit with the earth, or, more strictly speaking, with the water. As will be readily perceived therefore, in this case, a single wire only is needed to connect one element of the battery with the fuze, the other element being of course allowed to pass to earth. In the other description of torpedo, a *circuit closer* of the same construction is used, and this on being struck furnishes a signal to the shore, whence a sentinel at once explodes any charge, or charges, which may be in the vicinity of the submerged machine. When disconnected from the batteries, these torpedoes naturally cease to be a source of danger, and herein lies one of the most valuable qualities of the electric exploding method. If considered desirable, the machines need in fact never be put into an active state except in a case of imminent danger. Thus, if a fleet of friendly vessels were pursued by hostile ships, the sentinel on the look-out would not connect his batteries until the former had passed over the torpedoes, and when the machines were well left behind, by simply turning a switch arrangement he would be enabled instantly to close the line of defence, and set up a formidable barrier not to be passed with impunity.

In the simplest form of electric torpedoes (such as the majority of those used in America) where ignition is brought about by simply sending a current through the circuit, one wire leading from the torpedo to the battery and another to earth, the employment of the Abel fuze presents one very important advantage. Explosive machines fitted with these appliances may, when in position, be tested at any moment to ascertain their state of efficiency, and the operator is thus made cognisant of the serviceableness or otherwise of his apparatus and batteries; this operation is effected by simply passing a weak current through the wire and fuze, which although insufficient to produce ignition, is yet powerful enough for the transmission of signals.

Where a large number of torpedoes are grouped together, it is found undesirable, except in special cases, to use either the frictional or dynamo-electric machines for exploding the fuzes, for the reason that a current sent from one of these instruments to ignite a specific charge, induces similar currents in adjacent wires and at once causes a wholesale explosion. Constant voltaic batteries or piles are therefore generally resorted to, and the construction of simple forms of these from rough, handy materials (some sheet zinc and copper, a few pieces of wood, and a little vinegar and common salt) is a favourite occupation among sailors who have received elementary instruction in this system of warfare.

By employing in torpedoes, instead of powder, a heavy charge of gun-cotton, and exploding this by the newly-discovered method of detonation, a force is developed which, it is no exaggeration to say, would prove fatal against a vessel of the strongest and most cunning construction.

NOTES

WE are glad to be able to announce that the arrangements for the Eclipse Expedition are progressing very rapidly and satisfactorily, and that there seems every chance of everything being done which can insure success. In response to their circular, the Council of the Royal Astronomical Society have received upwards of sixty applications from observers anxious to help in an examination of the phenomenon. It is proposed that, if possible, there shall be two expeditions; one to Spain, the other to Sicily. The desirability of this is obvious, as the chances of bad weather are thereby considerably reduced. Unfortunately, those who know Sicily well state that the region to be visited is so brigand-ridden that other precautions besides those usually employed in Eclipse Expeditions will be desirable. The Italian Government, which will also, we believe, send an expedition to Sicily, will, doubtless, look to this. The French Expedition will observe in Algeria.

OUR Berlin Correspondent writes that Baron Liebeg has recovered from his recent severe illness.

WE regret to learn that Mr. Archibald Geikie, who recently left England to investigate the Geology of the Lipari Islands, was prostrated by fever as soon as he arrived there, and is in such a weak state of health, that he has been ordered back to England.

AN Imperial decree has been published in Paris, ordering that the Minister of Fine Arts shall henceforth bear the title of Minister of Literature, Science, and Art, and also that his department shall include the superintendence of the Institut de France, Academie des Sciences, the libraries, learned societies, and the like. When shall we get *our* Ministry of Literature, Science, and Art?

THIS will be a week of Anniversary Meetings. On Monday the annual réunion of the Royal Geographical Society will be held at one o'clock, and of the Victoria Institute at four; and on Tuesday the Linnean Society will celebrate its anniversary at three, and the Ethnological at four.

THE *British Medical Journal* states that the chair of Physiology, in the University of Prague, vacant by the death of the celebrated Purkinje, has been filled by the appointment of Dr. Hering, of Vienna. It was offered to Professor Helmholtz, who, however, preferred to remain at Heidelberg.

AT the annual meeting of the Newcastle Natural History Society on the 10th inst., a discussion took place on the present position of the Alder Memorial Fund. It was stated that while the original intention was to raise 600*l.* to carry out the memorial scheme, only about 300*l.* had been collected since March 1867. After some discussion, it was agreed to make efforts to raise an additional 100*l.*, which was considered a sufficient sum to carry out the objects proposed.

AT the recent general examination for women, held by the University of London, five passed in the "Honours" Division and four in the First Division. Of the seventeen candidates, five were from the Cheltenham Ladies' College, all of whom were successful, two being placed in the Honours and three in the First Division.

MR. J. W. ELWES, of King's College and the London University, and Mr. W. T. Sollas, of the Royal School of Mines, have been elected (equal) Exhibitioners in Natural Science, at St. John's College, Cambridge. There were eight candidates; the examiners being Prof. C. C. Babington (Botany), Prof. Humphry (Physiology), Prof. W. G. Adams (Physics), Mr. Bonney (Geology), and Mr. Main (Chemistry).

A RECENT number (94) of the German series known as "A Collection of Popular Scientific Treatises, edited by R. Virchow and Fr. von Holtzendorff," is a lecture on the Glacial Period (*Die Eiszeit der Erde*), by Alexander Braun. It gives a clear and concise history of the observations and arguments by which geologists have been led to the conclusion that a lengthened period of extreme cold overspread the greater part of Europe before the commencement of the historical epoch.

MR. C. P. SMITH reprints, as a separate publication, an epitome of a paper read before the Brighton and Sussex

Natural History Society on Nov. 11, 1869, under the title of "The Moss Flora of Sussex, together with Notes on the Structure and Reproduction of Mosses."

THE first volume is published of Dr. Oppolzer's "Lehrbuch zur Bahnbestimmung der Kometen und Planeten."

A PAMPHLET lies on our table entitled "History of Modern Anæsthetics, a second letter to Dr. Jacob Bigelow, by Sir J. Y. Simpson, Bart." Without entering into the merits of the controversy between the Scotch and American doctors, it is but just to the memory of Sir James Simpson to say that it appears to have been conducted by him in an admirable spirit of courtesy which is not always found in scientific discussions. It is admitted on both sides that the first case of an anæsthetic operation under sulphuric ether occurred at Boston on the 30th of September, 1846; and the first case of an anæsthetic operation under chloroform occurred at Edinburgh on the 15th of November, 1847. The last sentence of Sir James's letter to Dr. Bigelow, written when the grave was almost closing upon him, is full of touching pathos:—"With many of our profession in America I have the honour of being personally acquainted, and regard their friendship so very highly, that I shall not regret this attempt—my last, perhaps—at professional writing, as altogether useless on my part, if it tend to fix my name and memory duly in their love and esteem."

IN the *North American Review* for April appeared an article entitled "Darwinism in Germany," from the pen of Mr. Charles L. Brace, giving a *résume* of the present state of biological speculation on the Continent.

MR. WILLIAM HUGHES, Professor of Geography in King's College, London, reprints "Geography in its relation to History," a lecture delivered at the Birkbeck Institution; and "Geography, what it is, and how to teach it," a paper read before the College of Preceptors.

THE *Food Journal* for May commences a somewhat minute description of Mr. Twining's Museum of Domestic and Sanitary Economy at Twickenham, one of the most interesting and really valuable collections ever brought together by private enterprise.

DURING the present year, the following medals will be awarded for the encouragement of photographic discovery:—A large silver medal, by the French Photographic Society, for the best transparent pellicle that can be devised for the transfer of *cliches;* a large gold medal, by the Vienna Photographic Society, for the best dry process; and two silver and two bronze medals for other deserving inventions. The Hamburg Society also promises medals for important discoveries.

AT the sitting of the Paris Academy of Science for May 2, the President announced the death of Professor Lamé, a member of the Institute since 1843. The deceased, a very celebrated physicist and mathematician, was born in 1795, educated at the Ecole Polytechnique, and was for some time engineer in the Russian service. On his return to France, he was appointed Professor of Physics at the above-named school, and remained in that capacity until the year 1845, when he was elected Examiner at the school. In the year 1848 he was appointed Professor in the Faculty of Sciences at Paris. Among his very many published works those on mathematics and the elasticity of bodies are the most celebrated.

ACCORDING to the *British Medical Journal*, the weight of the late Sir James Simpson's brain, including the cerebellum, was 54 ounces. While, as is well known, the ratio between intellect and size of brain is by no means close, yet there can be no doubt that it is very important. Most of our great men have had large crania. The male brain ranges chiefly between 46 and 53 ounces, its average being $49\frac{1}{2}$ (Quain and Sharpey). That of Cuvier is stated to have weighed 64 ounces, and that of the late Dr. Abercrombie 63 ounces, but it is possible that some error may have crept in through the use of weights of different standards. If not, Sir James's brain, whilst much above the average, did not nearly reach those of the celebrated men we have mentioned; but at the same time, the convolutions were remarkably numerous; they were, says a correspondent, "twisting and twining round on each other as if they could not find room within the head. The island of Reil was very wonderful."

THE frontispiece to the *Photographic Art Journal* for May is the first published example of Mr. Woodbury's new patent process of photo-mechanical printing in printing-ink. It was printed in a copper-plate press from a plate produced at the establishment of MM. Goupil, at Paris. It is entitled "Orpheline," and is a copy of a drawing by Girardet, an eminent modern French artist. The other illustrations in the same journal are a photograph by Messrs. Edwards and Kidd's photo-mechanical or surface-printing process, of a drawing made at Chartres last October by Mr. A. E. Browne; and a copy by the photo-engraving process of M. H. Garnier, of Paris, of an old lithograph by the celebrated French painter Géricault.

AN interesting application of photography to legal evidence has just taken place. The Spanish Government having refused to give up the *Tornado*, an English vessel captured some time since, or to give compensation to the owners, our own Government has acquiesced in the decision, a photographic copy of the private instructions given to the captain by the owners having proved conclusively the more than doubtful character of the vessel.

THE *American Entomologist* for April appears under the new title of the *American Entomologist and Botanist*. Mr. Charles V. Riley continues the editorship of the entomological department, while the botanical section is undertaken by Mr. George Vasey, of Richview, Illinois, who has long been known in the West as a careful botanist. The paper is published at the enterprising south-western capital, St. Louis, Missouri, a town which also supports the *Grape Culturist*, a monthly journal devoted exclusively to grape culture and wine making, and the *St. Louis Journal of Agriculture*, published weekly. An epitome of its contents will be found under the head of "Scientific Serials."

AT a recent meeting of the Paris Chemical Society, M. Scheurer-Kestner read a paper on the composition of fossil and recent bones. He finds that bones which have been buried for long periods contain, besides ossein, which is insoluble in water, another organic nitrogenous substance, soluble in water, and into which he supposes ossein to be slowly changed. Running water gradually removes this soluble modified ossein, and consequently the ancient bones found in loose impervious soils contain very little organic matter, while those buried in compact clay may retain a large quantity of it. The rate of decomposition thus varies with the nature of the soil; but in the same soil M. Scheurer-Kestner believes that the relative age of different bones can to a considerable extent be determined by their chemical composition.

THE *Scientific American* states that Mr. Sherwood has invented an ingenious method for the separation of animal fibre from vegetable. The process does not alter the colour or structure of the animal fibre, and permits the use of cotton or linen separated from it for numerous purposes. It is sufficient to suspend the goods in an atmosphere of nitrogen or carbonic acid, and to cause the vapour of perfectly dry sulphuric, phosphoric, or hydrochloric acid to enter the room. These fumes disentangle the vegetable fibre, and leave intact the animal—the two fibres can thus be separated and appropriated to their respective uses.

ACCORDING to the *Chamber of Agricultural Commerce*, Belgium sent us during the year 1869 3,000 tons of meat, poultry, and rabbits; and the birds, at any rate, we might as well have fed and hatched at home. Belgium exported in the same year 34,375 tons of raw beet-root sugar. What prevents us making sugar for ourselves in the United Kingdom? Certainly not climate, for the Hon. Agar Ellis, M.P., has grown sugar-beets this year in several parts of Kilkenny county; and Dr. Völcker's analysis of the roots finds a proportion of 8·94 to 10·91 per cent. of crystallisable sugar, while a proportion of only 8·5 per cent. is said to be sufficient to remunerate the sugar manufacturer. The sugar-beets grown near Lavenham, Suffolk, in 1868 contained, according to the same analyst, from 9·62 to 12·84 per cent. of crystallisable sugar.

A PARLIAMENTARY return has just been issued showing to what extent the Act for establishing libraries and museums has been adopted. At Manchester the Public Free Library was opened on the 6th of September, 1852; the public subscription amounted to 12,823*l.*, of which 813*l.* 18*s.* was contributed by artisans and workpeople, numbering upwards of 20,000 persons employed in the various industrial establishments in the city and neighbourhood. On the question of maintaining the library, the number of votes recorded in favour of the adoption of the Act was 3,962; against its adoption, 40. The news-rooms during the evening hours are constantly crowded; from the published tables it appears that the total number of readers had increased from 39,944 in 1853 to 135,877 in 1868. Between 1863 and 1864 the numbers fell from 91,121 to 58,589, showing to how great an extent the libraries are used by the classes affected by the cotton famine. The number of borrowers, though subject to a slight fluctuation at the same period, has shown a comparatively steady increase from 2,000 in 1853 to 27,749 in 1868. The daily average of visitors in 1868 was 5,575, or upwards of 1,700,000 during the year. The total number of volumes in the library in June 1869, was 40,498 in the reference library, and 49,791 in the lending department.

THE Prussian Government appears to have definitely decided on introducing the Vautherin (iron) sleepers in the place of wood on the State railways. A contract has been recently entered into with the Saarbrück works, for the supply of 30,450 sleepers, intended for the railways from Trèves to Saarbrück, from Saarbrück to Neunkirchen, and from Neunkirchen to Bingerbrück. By this means it is thought also that the inconvenience will be avoided which has been experienced in France from the excessive destruction of the forests, and the great excess of the consumption of timber over the native production.

THE gradual destruction of fish in the rivers of Germany by the unrestricted fisheries has begun to attract serious attention, and the evil is beginning to be felt also in the coast fisheries. M. Schmarda, who has been commissioned by the Austrian Government to inspect and report on the French fisheries, estimates the quantity of fish caught on the coast between Cherbourg and Toulon at upwards of 58,000,000 kilogrammes in the year.

IT is stated that the Roman Catholics of San Francisco are building an "earthquake-proof" church. The side walls above the basement are only 30 feet high; at this height a roof rises, which, with the main roof, is supported independently of the walls, by two rows of pillars inside of them. Both roofs are firmly bound to the pillars, and the pillars are fastened together by iron cross-beams, secured with heavy iron bolts, forming a network of great strength. The theory of the plan of construction is, that should the pillars be shaken down, the roof would be launched outside the walls, thus giving a chance of escape from the ruins. In thus falling, the roof would be carried aside a distance of 80 feet, the length of the pillars.

IT can scarcely be said that any amount of water is too great for the supply of public and private wants, but as the expenses increase rapidly with the volume supplied, a limit is in practice soon reached and cannot readily be exceeded. The average amount of water consumed per diem for each person is estimated at about three-and-a-half pints, below which proportion physical suffering commences. The quantity required for washing purposes is estimated at about one gallon. A considerable quantity is also required for the consumption of animals, for watering the streets, gardens, &c., the extinction of fires, and other purposes. The following table shows the quantity supplied in different cities to each inhabitant per diem, expressed in litres (=1·7 pints).

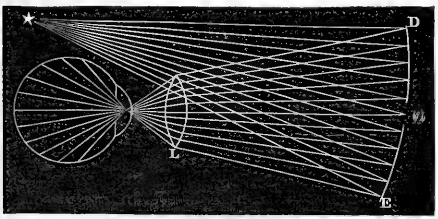
THE *Field* quotes the following from the *Toronto Globe*, illustrative of the much-disputed fact that the queen-bee can be fertilised within the hive. The observer is Mr. Malone, of Garden Island:—"I first made some small nuclei hives, and inserted three frames in each (with brood and comb in them), and placed a queen cell in each in such a manner that by turning a button I could see the cell. As soon as the queen was hatched I caught her and placed her in a cage 6in. square by 8in. long, two sides of the cage being wood, the rest wire, and placed a good number of worker bees in with her, and put the cage on the top of the frames in a hive containing a good swarm of bees, having first removed their queen. When the queen was five days old, that is, on the fifth day, I took out all the worker bees from the cage, and placed seven nice large drones in with the queen. I left the queen and drones together forty-eight hours in the cage, having placed them back again on top of the frames, and replaced the cover and plugged up the ventilators which are in the sides of the cover, to keep out the light. Of course I put some honey in the cage, out of the reach of the bees below in the hive, to keep the queen and drones from starving. Each time on examination, I found (with one exception) a dead drone, having all the end of his abdomen burst open, and twice I noticed evidences of impregnation. To make myself doubly sure that they were fertilised by this method, I introduced the queens into new swarms, and closed the opening so that nothing but a worker bee could go in and out, and all the queens (with one exception, as mentioned above) in a few days commenced laying, and reared nicely-marked Italian workers."

THE REV. E. O'MEARA, A.M., is preparing a catalogue of Irish Diatomaceæ. This catalogue will appear in the form of a report to the Royal Irish Academy, and will, we presume, be published in its Transactions. A synonymy of all the species will be given, and figures of all the new species, or of species the figures of which are not easily accessible. This catalogue, which will be the result of many years' labour, will, we believe, form a worthy supplement to "Smith's British Diatomaceæ."

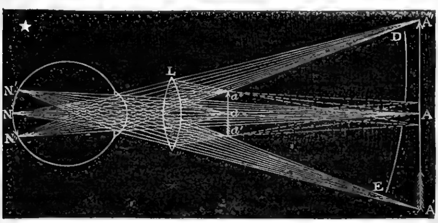
COMPLAINTS have appeared in some of the Dublin papers that the library of the Royal Dublin Society was closed for a week during the Dublin Cattle Show. It is also rumoured that a complaint of the same kind was forwarded to the authorities at Kensington. When it is recollected that this is, perhaps, the only equally large library in Europe that is open to the public from 10 A.M. to 10 P.M. throughout the year, it will be seen that the public have little real cause of complaint in its being closed for eight or ten days in the twelve months.

A NEW FORM OF OPHTHALMOSCOPE

THE principal steps that have been made during the last twenty years in the knowledge of the healthy and of the diseased conditions of the eye have been effected by the employment of the ophthalmoscope, an instrument so simple, and yet so valuable, that, like other discoveries, it is only remarkable that the knowledge of the facts on which its construction depends should have so long remained unfruitful. Under all ordinary circumstances, when we look into the pupil of the eye of another person, however widely dilated it may be, it appears of an intense black hue, because the degree of illumination is insufficient to render parts so deeply seated visible, the principal portion of the light being intercepted by the head of the observer. An exceptional instance, however, is sufficiently familiar to every one, in which a brilliant reflection may be observed to occur from the back of the eye. It is that of an animal crouching in the corner of a cellar, whilst the observer is standing at the door, or looking towards a window, to which the back of the observer is turned. The principle on which the ophthalmoscope is founded is identical with this, the eye under observation being illuminated by a pencil of light proceeding, as it were, from the eye of the observer. This is accomplished by placing a steady source of light at the side of or above and somewhat behind the head of the person under observation, whilst the observer reflects its rays into the eye of the subject by means of a plane or concave mirror, the centre of which is perforated by a small opening through which he looks. The back, or fundus of the globe, then comes into view, presenting a red, or greyish red glare, the illumination being greatly increased by the use of a lens at L, as shown in the accompanying little



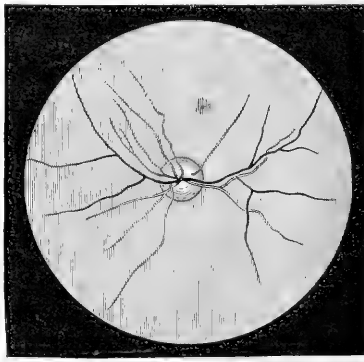
woodcut, from the recent work of Dr. Williams of Boston, where the rays of light emanating from the star are reflected from the concave mirror DE, and rendered convergent by the lens L, lighting up the whole of the posterior surface of the globe; some of the rays returning from this pass through the opening in the mirror, and are seen by the observer at O. The precise mode in which the image is formed is shown in the following cut, borrowed



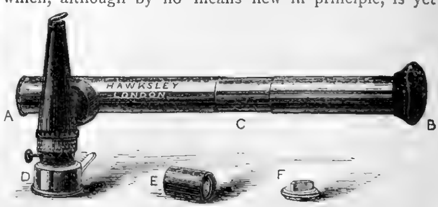
from the same work. The rays returning from N, N′ N″ representing a portion of illuminated fundus, are brought to a focus by the convex lens L, at A, A′ A″, and then form, the inverted aërial image of the fundus, which is seen by the observer.

The image which comes into view under these circumstances, especially if, as is usual, the pupil be dilated by the employment of a little belladonna or solution of atropine, is represented in the following woodcut, which we have carefully drawn from a child of twelve years of age. The reader must imagine the general surface to be of an orange vermilion, or scarlet vermilion tint, though in the negro it is of a very dark vermilion; the colour being produced by the reflection of the light from the capillary blood-vessels of the choroid.

In the centre is a yellowish white spot, which is the optic disc, or point of entrance of the optic nerve. This is perforated by the branches of the central artery and veins of the retina, the lighter double lines representing the arteries and the darker the veins. Above and a little to the right is a spot which is the true centre, and at the same time the most sensitive part of the eye; from its colour it is sometimes called the macula lutea, or from its being



slightly depressed below the surface it is termed the fovea centralis. The changes which the optic disc, the blood-vessels, and the retina undergo in disease can of course be readily followed, and may thus enable a positive opinion to be pronounced on cases which were formerly incapable of being distinguished even by the most acute observer. Nay, it has recently been suggested by M. Poncet to employ it as one of the most reliable means of ascertaining that *death* has really taken place. A great variety of forms of the instrument have been suggested, but the ordinary hand ophthalmoscope has proved the most convenient in practice, requiring only that the room should be darkened, and that there should be some steady source of light. Dr. Beale, however, has lately suggested a form of self-illuminating ophthalmoscope, which, although by no means new in principle, is yet



convenient in application, doing away with the necessity of a dark room, and furnishing a very steady and good light. It is represented in the preceding figure, and consists of a tube, A B C, of which the extremity B is closely applied to the eye to be examined, thus shutting out all extraneous light. D is a paraffin lamp which can be easily connected or removed, the rays falling on a perforated mirror, and being reflected towards B, a convex lens being interposed near C, which can be approximated to or made to recede from the eye by the movement of the draw-tube B.

We have tried the instrument in a number of cases, and have found that while it enables a very good view of the fundus to be obtained with facility, it has the drawbacks of smelling disagreeably and also of becoming rather unpleasantly hot, from the proximity of the lamp to the eye of the observer—an inconvenience that might be remedied by placing the lateral tube at a greater distance from the end A.

SCIENTIFIC SERIALS

THE PROGRESS OF CHEMISTRY (*Jahresbericht über die Fortschritte der Chemie und verwandter Theile anderer Wissenschaften.*) Unter Mitwirkung von Th. Engelbach, Al. Naumann, W. Städel; herausgegeben von Adolph Strecker. Für 1868. Erstes Heft. Ausgegeben am 15 Februar, 1870. Giessen J. Ricker'sche Buchhandlung. 1870.

Of the 480 pages of this part, 133 are occupied by general and physical, and 155 by inorganic chemistry, the remainder being devoted to organic chemistry.

In the first section we find an account of the method devised by Hofmann for determining the vapour densities of solids and liquids in a Torricellian vacuum, and which promises such valuable results in many cases. Tomlinson's observations on the properties of chemically clean surfaces are here noticed; and also Guthrie's experiments on the conduction of heat by liquids. A long abstract of Becquerel's papers on electro-capillary action opens the section on electro-chemical investigations, and in the division on optical chemistry Tyndall's researches on the chemical action of light find a place. Two of the channels into which much chemical thought has been directed during the last few years are clearly indicated by the notices of numerous papers on dissociation and spectrum analysis.

In the section on inorganic chemistry we have some additional experiments in support of Frankland's theory of the cause of the light emitted by luminous flames; the combustion of hydrogen and carbonic oxide in oxygen under a pressure of ten atmospheres, and the burning of heated phosphorus vapour in hot chlorine being mentioned. Graham's researches on the occlusion of hydrogen by metals, and on the curious combination which this element forms with palladium are noticed at considerable length. The next paper to which we shall direct attention is one which at present stands amongst those on inorganic chemistry, but the compounds herein described bid fair shortly to occupy a section by themselves in a position intermediate between mineral and organic bodies; we refer to the researches of Friedel and Ladenburg on silicic oxychloride, and silicium iodoform; the study of compounds having the same constitution as well-known organic bodies, but in which silicon plays the part of carbon, promises to enable us, ultimately, to explain the constitution of that very extensive class of complex bodies containing silicon, which are found so abundantly in nature. We have a long notice of Meyer's investigations of indium and its compounds, and one on Mills's researches on the ammoniacal cobalt compounds.

Among the papers on organic chemistry, we have that of Troost and Hauteufeille, on the decomposition of mercuric cyanide at different temperatures and pressures; and the very important one by Berthelot on the synthesis of hydrocyanic acid, which he obtained by the passage of electric sparks through a mixture of acetylene and free nitrogen. A considerable space is devoted to the researches of Jungfleisch on the chlorine derivatives of benzol, and to Oppenheim's investigations of the isomeric compounds of allyl and propylene. Berthelot's valuable researches on the hydrocarbons are continued, his observations on styrol and its compounds being given. The foundation of one of the most interesting and valuable discoveries of the last few years is contained in this volume, viz., the conversion of alizarin into anthracene by its distillation from powdered zinc. Since this paper was published, its authors, Messrs. Graebe and Liebermann, have succeeded (as our readers well know) in effecting the inverse transformation, and thus producing the colouring principle of madder from one of the products of the destructive distillation of coal. We also find here the discovery of the first acetylene of the aromatic series, by Glaser in acetenylbenzol or phenylacetylene. Linnemann's preparation of normal propylalcohol and the synthesis of butylalcohol by Lieben, are noticed, as are the researches of Stenhouse on tetra- and tri-chlorochinon.

All students of chemistry will heartily welcome the appearance of the Jahresbericht, though the usefulness of the first part is much impaired for want of the index. It is very much to be regretted that this very valuable book does not appear at an earlier date; in this case the first part of the report has been published thirteen months and a half after the expiration of the year to which it refers. It must be allowed that the labour required for such a work is very arduous, but it would be a great convenience to chemists if it were possible to expedite its publication. It is reported that the Council of the Chemical Society of London intends to issue fortnightly, or monthly, short abstracts of all papers on chemistry and the allied sciences published in England and abroad. These abstracts will be made by competent chemists, and will be printed as soon as possible after the appearance of the original memoirs. Such a collection of abstracts would be invaluable to many who, in consequence of their living away from London, or owing to other circumstances, have no opportunity of reading the periodicals: it would also be extremely useful to many who, though within reach of journals, have not the time to devote to the perusal of the very numerous papers published at the present time. All chemists, and many others taking a general interest in science, must wish every success to the efforts of the Council of the Chemical Society, though it is to be feared that such a journal would scarcely, at present at least, prove a commercial success.

THE *Revue des Cours Scientifiques* for May 7 contains M. Blanchard's lecture before the *Réunion des Sociétés Savantes*, at the Sorbonne, on Scientific Work in the Departments; the continuation of Bernard's lecture on Suffocation by Charcoal fumes; and the conclusion of M. Bouley's on Madness. In the number for May 14 we find M. Kuhne's lecture on the Science of Life, delivered on the occasion of the inauguration of the Physiological Laboratory at the University of Amsterdam; a paper by M. E. Fournier on the Ergot of Rye, being the first of a series on the parasites of cereals; and a continuation of M. Bernard's paper.

THE *American Entomologist and Botanist* for April contains several good articles. A paper entitled "Wheat-rust and barberry rust" (placed singularly in the entomological department), defends the accuracy of the statement well known to European botanists, but which appears to have been attacked in America, that the neighbourhood of barberry trees is a prolific cause of rust in wheat; the fungus which causes the latter disease, *Puccinia graminis*, and the fungus which produces the bright yellow spots on the leaves of the barberry, *Œcidium berberidis*, being, in fact, different conditions of the same plant. An article entitled "Scientific Language," justly rebukes the tendency to use long latinised words where plain English words would do just as well, and especially the coining of barbarous compound terms, derived from two or three different languages. There are also several good descriptive papers, both entomological and botanical, specially interesting to American naturalists and collectors.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, May 2.—Mr. A. R. Wallace, president, in the chair. Mr. Hewitson exhibited a collection of new and rare butterflies, from Tropical America.—Mr. Frederick Smith exhibited a collection of *Hymenoptera*, from Japan.—Mr. McLachlan exhibited some exotic dragon-flies.—Mr. Bates exhibited several new exotic *Copridæ*.—Mr. G. R. Crotch sent for exhibition British specimens of *Trachyphlœus laticollis*, a beetle not previously recorded as indigenous to this country.—Papers were read, on Equatorial *Lepidoptera*, by Mr. Hewitson; on some new *Neuroptera Odonata*, by Mr. McLachlan; on new *Copridæ*, by Mr. Bates; and on Australian *Curculionidæ*, by

Mr. Pascoe.—"A Catalogue of British Neuroptera," compiled for the society by Mr. McLachlan, and published by the society, was on the table.

Ethnological Society, May 10.—Special meeting held at the Museum of Practical Geology, by permission of Sir R. I. Murchison, Bart. Prof. Huxley, LL.D., F.R.S., in the chair. Dr. O'Callaghan was announced as a new member.—Col. Lane Fox read a letter from Lieut. Oliver, R.A., relative to the destruction of the fine menhir of Le Quesnel, in Jersey, described in the last number of the Society's Journal.—Sir J. Lubbock, Bart., and Mr. J. S. Mackie made remarks on the importance of the labours of the society in obtaining reports on the present condition of our megalithic monuments.—Prof. Huxley then delivered an address on the Ethnology of Britain. He showed that the early accounts of the inhabitants of these islands, such as that given by Tacitus, prove the existence of two types of people physically distinct—the one being tall, fair, yellow-haired, and blue-eyed, whilst the other was short and dark, with dark hair and black eyes. This dark type, as exemplified in the ancient Silures, closely resembled the people of Aquitania and Iberia, whilst the fair type of south-east Britain was physically related to the Belgæ of north-east France and what is now Belgium; and these again resembled the old Germani, who dwelt on the east bank of the Rhine. In this country both the fair and the dark people spoke Celtic—probably Cymric in Britain and Gaelic in Ireland. But on the Continent the dark type spoke a Euskarian or Basque tongue, while the ancient Gauls spoke Celtic and the Germani Teutonic. The Celtic and Teutonic languages both belong to the Aryan family, but the Euskarian appears to have no affinity to any other Eur-asiatic language. None of the invasions to which Britain has been subjected has introduced any new race-element. It is doubtful whether the Romans strengthened the fair or the dark type of the pre-existing population, but it is certain that the invasion of the Low Dutch from the shores of North Germany bordering on the Baltic and the North Sea strengthened the fair element, as also did the incursions of the Danes. The effect of the Norman conquest would be shown by Dr. Nicholas.—The Rev. Dr. Nicholas then read a paper "On the Influence of the Norman Conquest on the Ethnology of Britain." He first inquired what race-elements were present in Britain prior to the Conquest, and concluded that the blood preponderated considerably in favour of the ancient British race—a race which he did not hold to be purely Celtic. He then sought to determine what were the elements in William the Bastard's so-called "Norman" army, and showed that they were mainly Gaelic and Cymric. Hence the conclusion that the effect of this conquest was in the gross greatly gainful to the old British or Gallo-Celtic population.

MANCHESTER

Literary and Philosophical Society, March 22.—The following extract of a letter, dated March 21, 1870, from Sir William Thomson, D.C.L., F.R.S., hon. member of the Society, was read:—

"I have now at last got into good working order measurements of electrostatic capacity (which, perhaps, you may remember I was working on the first time you ever came to see me, and more or less almost ever since). I have two students of last year, junior assistants in my laboratory, measuring electrostatic capacities of condensers, and variations of specific inductive capacities of resistance, with sensibility of $\frac{1}{10}$ per cent., and with constancy in spite of accidental variations, generally within $\frac{1}{4}$ or $\frac{1}{3}$ per cent. My occupation on the Kinetic theory of gases has led me at last to come to definite terms as to the size of molecules. Ever since about the first year of my professorship I have taught my students that Cauchy's theory of Dispersion proves heterogeneousness, or molecular structure, to become sensible in contiguous portions of glass or water, of dimensions moderately small in comparison with the wave-lengths of ordinary light. I have spoken to you also, I think, of the argument deducible from the contact electricity of metals. This, I now find, proves a limit to the dimensions of the molecules in metals quite corresponding to that established for transparent solids and liquids by the dynamics of dispersion. In experiments made about ten years ago, of which a slight sketch is published n the Proceedings of the Literary and Philosophical Society of Manchester, I found that a plate of zinc and a plate of copper kept in metallic connection with one another (by a fine wire or otherwise) act electrically upon electrified bodies in their neighbourhood, and upon one another, as they would if they were of the same metal and kept at a difference of potentials equal to about three-quarters of that produced by a single cell of Daniell's. Hence, and from my measurement of the electrostatic effects of a Daniell's battery, published in the Proceedings of the Royal Society, for February and April, 1860, I find that plates of zinc and copper held parallel to one another at any distance, D, apart which is a small fraction of the linear dimensions of their opposed surfaces, and kept in metallic communication with one another, exercise a mutual attraction equal to

$$2 \times 10^{-10} \times \frac{A}{D^2} \text{ grammes weight.}$$

Hence, if they were allowed to approach from any greater distance, D', to the distance D, the work done by their mutual attraction is

$$2 \times 10^{-10} \times \frac{A(D'-D)}{D'D} \text{centimetre grammes;}$$

which, if D is very small in comparison with D', is very approximately equal to

$$2 \times 10^{-10} \times \frac{A}{D}$$

Now suppose a pile to be made of a great number (N + 1) of very thin plates alternately of zinc and copper, kept in metallic connection while they are brought towards one another. Let their positions in the pile be parallel, with narrow spaces intervening. For simplicity let the thickness of each metal plate and intervening space be D. The whole work done will be

$$2 \times 10^{-10} \times N\frac{A}{D}$$

The whole mass of the pile (if we neglect that of one of the end plates) is

$$NAD\rho,$$

where ρ denotes the mean of the densities of zinc and copper. Hence, if h be the height to which the whole mass must be raised against a constant force equal to its weight at the earth's surface, to do the same amount of work, we have

$$NAD\rho h = 2 \times 10^{-10} \times N\frac{A}{D}$$

which gives

$$h = \frac{2 \times 10^{-10}}{\rho D}$$

or, as $\rho = 8$, nearly enough for the present rough estimate,

$$h = \frac{1}{(200000D)^2},$$

Hence, if

$$D = \frac{1}{200000} \text{ centimetre,}$$
$$h = 1 \text{ centimetre.}$$

The amount of energy thus calculated is not so great as to afford any argument against the conclusion which general knowledge of divisibility, electric conductivity, and other properties of matter ndicates as probable: that, down to thicknesses of $\frac{1}{200000}$ of a centimetre for the metal plates and intervening spaces, the contact electrification, and the attraction due to it, follow with but little if any sensible deviation the laws proved by experiment for plates of measurable thickness with measurable intervals between them. But let D be a two-hundred-millionth of a centimetre. If the preceding formulæ were applicable to plates and spaces of this degree of thinness we should have

$$h = 1{,}000{,}000 \text{ centimetres or 10 kilometres.}$$

The thermal equivalent of the work thus represented is about 248 times the quantity of heat required to warm the whole mass (composed of equal masses of zinc and copper) by 1° Cent. This is probably much more than the whole heat of combination of equal masses of zinc and copper melted together. For it is not probable that the compound metal when dissolved in an acid would show anything approaching to so great a deficiency in the heat evolved below that evolved when the metallic constituents are separately dissolved, and their solutions mixed; but the experiment should be made. Without any such experiment, however, we may safely say that the fourfold amount of energy indicated by the preceding formula, for a value of D yet twice as small, is very much greater than any estimate which our present knowledge allows us to accept for the heat of combination of zinc and copper. For something much less than the thermal equivalent of that amount of energy would melt the zinc and copper; and, therefore, if in combining they generated by their mutual attraction any such amount of energy, a mixture of zinc and copper filings would rush into combination (as the ingredients of gunpowder do) on being heated enough in any small part of the whole mass to melt together there. Hence we may infer that the electric attraction between metallically-connected plates of zinc and copper of only $\frac{1}{400000000}$ of a centimetre thickness, at a distance of only $\frac{1}{400000000}$ of a centimetre asunder, must be greatly less than that calculated from the magnitude of the force and the law of its variation observed for places of measurable thickness, at measurable distances asunder. In other words, plates of zinc and copper so thin as a four-hundred-millionth of a centimetre from one another, form a mixture closely approaching to a molecular combination, if, indeed, plates so thin could be made without splitting atoms. Wishing to avoid complication, I have avoided hitherto noticing one important question as to the energy concerned in the electric attraction of metallically connected plates of zinc and copper. Is there not a change of temperature in molecularly thin strata of the two metals adjoining to the opposed surfaces, when they are allowed to approach one another, analogous to the heat produced by the condensation of a gas, the changes of temperature produced by the application of stresses to elastic solids which you have investigated experimentally, and the cooling effect I have proved to be produced by drawing out a liquid film which I shall have to notice particularly below? Easy enough experiments on the contact electricity of metals will answer this question. If the contact-difference diminishes as the temperature is raised, it will follow from the Second Law of Thermodynamics, by reasoning precisely corresponding with that which I applied to the liquid film in my letters to you of February 2nd and February 3rd, 1858,* that plates of the two metals kept in metallic communication and allowed to approach one another will experience an elevation of temperature. But if the contact difference increases with temperature, the effect of mutual approach will be a lowering of temperature. On the former supposition, the diminution of intrinsic energy in quantities of zinc and copper, consequent on mutual approach with temperature kept constant, will be greater, and on the latter supposition less, than I have estimated above. Till the requisite experiments are made, further speculation on this subject is profitless: but whatever be the result, it cannot invalidate the conclusion that a stratum of $\frac{1}{200000000}$ of a centimetre thick cannot contain in its thickness many, if so much as one, molecular constituent of the mass. Besides the two reasons for limiting the smallness of atoms or molecules which I have now stated, two others are afforded by the theory of capillary attraction, and Clausius' and Maxwell's magnificent working out of the Kinetic Theory of gases. In my letters to you already referred to, I showed that the dynamic value of the heat required to prevent a bubble from cooling when stretched is rather more than half the work spent in stretching it. Hence, if we calculate the work required to stretch it to any stated extent, and multiply the result by $\frac{3}{2}$, we have an estimate, near enough for my present purpose, of the augmentation of energy experienced by a liquid film when stretched and kept at a constant temperature. Taking ·08 of a gramme weight per centimetre of breadth as the capillary tension of a surface of water, and therefore ·16 as that of a water bubble, I calculate (as you may verify easily) that a quantity of water extended to a thinness of $\frac{1}{200000000}$ of a centimetre would, if its tension remained constant, have more energy than the same mass of water in ordinary condition by about 1,100 times as much as suffices to warm it by 1° Cent. This is more than enough (as Maxwell suggested to me) to drive the liquid into vapour. Hence if a film of $\frac{1}{200000000}$ of a centimetre thick can exist as liquid at all, it is *perfectly certain* that there cannot be many molecules in its thickness. The argument from the Kinetic Theory of gases leads me to quite a similar conclusion.

April 19.—Annual meeting, Dr. J. P. Joule, F.R.S., President, in the chair. The report of the council having been read, the following gentlemen were elected officers of the society for the ensuing year:—President: E. W. Binney, F.R.S., F.G.S.; Vice-presidents: Dr. J. Prescott Joule, F.R.S., Dr. E. Schunk, F.R.S., Dr. R. Angus Smith, F.R.S., Rev. W. Gaskell, M.A.; Secretaries: Dr. H. E. Roscoe, F.R.S., &c., J. Baxendell, F.R.A.S.; Treasurer: T. Carrick; Librarian: C. Bailey. Of the Council: P. Spence, F.C.S., G. Venables Vernon, F.R.A.S., J. B. Dancer, F.R.A.S., W. Leeson Dickinson, H. Wilde, R. Dukinfield Darbishire, F.G.S. A paper on "Infant Mortality in Manchester" was read by Mr. J. Baxendell, F.R.A.S., who combated the assertion that the high death-rate of Manchester and other towns in the cotton manufacturing districts is due to the mortality among infants and young children being relatively much greater than in large towns in other parts of the country, a careful examination of the mortality returns showing that a much larger proportional number of deaths of infants and young children takes place in other towns, where the general death-rate is decidedly lower.

* Proceedings of the Royal Society for April, 1858.

Cambridge

Cambridge Philosophical Society, May 2.—Clement Higgins, B.A., Downing College, was elected a fellow. Communications:—By Professor Miller, F.R.S.: "On the best form for the ends of measures *à bouts.*" The author found that the best form was that of two 'knife edges,' whose edges were in planes perpendicular to each other, and were not straight lines, but arcs of circles, whose centre was the opposite end of the axis of the bar. With this form the error (l being length of bar, and e distance between real and assumed position of the point where the axis intersects the bounding surface) $= \frac{e^4}{4l^3}$ while in the forms commonly used it was either $\frac{e^2}{l}$ or $\frac{2e^2}{l}$

By Mr. Bonney (St. John's College): Note on supposed Mollusc Borings in the limestone of Derbyshire. The author first described a large number of burrows which he had examined in the hills above Matlock; these were generally directed upwards, and too irregular in form to be *Pholas* burrows, as had been asserted; he then described some burrows observed in a scarp of limestone about nine feet above the stream in Miller's Dale, by the road-side. He believed this scarp to be artificial; but whether so or not, the gorge was most distinctly one of fluviatile erosion, and he maintained that this case was fatal to the *Pholas* theory. He considered the burrows to be the work of *Helices.*

Brighton

Brighton and Sussex Natural History Society, April 14.—Mr. Glaisher, Vice-president, in the chair. A communication from Mr. Gwyn Jeffreys respecting the Sars testimonial, was read by the Hon. Sec., after which a subscription was made among the members present, the Society not having power to vote its own funds for such a purpose. Mr. T. H. Hannah, the President, read a report on "Soundings made by Sir (Captain) E. Parry in 1818." These soundings were purchased some years since among the geological specimens of Sir E. Parry, from his widow, by Mr. J. Cordy Burrows, of Brighton, who deposited the geological specimens in the Brighton Museum, and gave the soundings to Mr. Peto. The discoveries of last year giving a prominence to sea-soundings, they were placed in January in Mr. Hannah's hands to examine microscopically, and report on their contents to the society. The soundings were made in Davis's Straits, and Lancaster Sound between 68° and 71° 15′ N. lat. and 73° and 78° 34′ W. long. at depths between 22 fathoms and 1,058 fathoms. Those under 58 fathoms contained nothing but stones and corals, some of the stones had evidently been rubbed by the action of a strong current; those from 201 fathoms were much less disturbed and consisted chiefly of a sandy material; from 674 fathoms there was an almost absence of inorganic débris, showing the non-existence of currents, and plenty of the testa of arenaceous foraminiferæ. In all the deep ones diatomaceæ were very beautiful, as well as sponge spicules and arenaceous foraminiferæ; but polycystinæ and cretaceous foraminiferæ were but sparsely found. He had also met with casts similar to those found in the greensand, and some highly organised spicules which he had not yet identified. At one of the microscopical meetings the slides would be exhibited. He much regretted they were not examined earlier, as they would then have preceded the discoveries of Carpenter and others, who, by the deep-sea soundings recently made, had opened out new ideas of life at great depths. Reference was then made to what had been done by Carpenter, Jeffreys, Thomson, and others in adding to our knowledge of the conditions of existence in deep sea; the nature of the animals and their economy together with the chemical conditions at great depths were also touched on, and the fact pointed out that changes of fauna depended not on latitude, but on the variations in the bottom temperature.—Mr. Wonfor, hon. sec., announced that the "Moss Flora of Sussex" was ready for distribution among the members, and that duplicate copies could be had at a nominal price, by applying to him, at 38, Buckingham-place, Brighton.

DUBLIN

Natural History Society of Dublin, May 4.—W. Andrews, Chairman of the Natural History Committee of the Royal Dublin Society, in the chair. The Chairman read a paper entitled "Ichthyological Notes." There are no subjects fraught with greater interest than discoveries which arise from a practical knowledge of any branch of science, whether it relates to botany, geology, or to any of the orders or genera of zoological investigations. When we contemplate the vast scope of the branches of the natural sciences, we cannot fail to meet most perplexing difficulties in the determining of correct classification, the opportunity of practical investigation not being afforded, for without that most essential aid, no certainty can possibly be arrived at, especially true characteristics depending upon habit, geographical range, seasons, depths, and peculiarities of soundings, and those natural causes which influence forms and changes of animal and vegetable life. The subject of the paper this evening relates to deep-water species, the present observations being with reference to notes on some fish occurring on the south-west coast of Ireland, in Dingle Bay, and off the coast of Kerry. Some most interesting crustaceans and species of rare fish have been met with, which are confined to peculiar soundings in deep water; yet I may say that at a depth beyond eighty fathoms much of interest as to variety of forms ceases, and the dredge in soundings of 100 fathoms, and beyond that depth, rarely brings up anything but remains belonging to shallower soundings, or those forms of Foraminifera Globigerina, which require microscopic manipulation in the determining of their numerous forms. It is singular, however, from what extreme depths minute crustacea, echinoderms, sponges, and corals are brought up; therefore I may say that when we proceed further than a depth of eighty fathoms, the interest, so far as the ichthyologist is concerned, closes. The object of this paper is to bring to notice a most interesting species of the Clupæidæ, the true anchovy (*Engraulis encrasicholis*) the first placed on record as captured on the shores of Ireland. I had heard of a species of small herring that had been taken in the herring nets, of a peculiar silvery brightness. I was delighted to obtain a specimen last autumn off Ventry Harbour, being another among the many interesting additions that have been made on that part of the coast of fish peculiar to the Mediterranean. The specimen exhibited is of full size, being in length six inches, thicker in proportion than the herring, no serrations on the abdomen, and the sides and belly being of the most silvery brightness, with no apparent scales. The back was a dark bluish green; the mouth with a remarkably wide gape; teeth exceedingly minute in the maxillary; none in the lower jaw; snout much projecting. At first examination I thought it might be a species of melletts, as it did not bear sufficient resemblance to several of the figures of the anchovy in works on ichthyology.—Dr. Foot then read a paper on the breeding of the Cereopsis Geese and Emus, in the Zoological Gardens, Dublin, and also laid before the meeting a paper on "Animal Luminosity," after which the meeting adjourned.

Royal Irish Academy, Monday, May 9.—Rev. Professor Jellett, B.D., president, in the chair. Dr. Stokes, V.P., F.R.S., read a paper on putrefaction occurring in some closed cavities, without the admission of air, and on the germ theory of Professors Lister and Tyndall.

Royal Geological Society, Wednesday, May 11.—Mr. G. Sanders, in the chair. Rev. Professor Haughton, M.D., read a paper on the probable geological effects of the permanent opening of the Suez and Darien Canals. The author regarded the Suez Canal as an interference with nature. He gave a graphic description of the two oceans, the Atlantic and Indian, with their two great offshoots, the Mediterranean and the Red Sea—seas with not a very limited rainfall area, and subject to immense evaporation; in fact, having all the circumstances in their favour to make them the seat of strong currents, the natural tendency of the meeting of which is to build up that vast sand or mud bar, the Isthmus of Suez. The new canal he regarded as a scratch of a spade by the hand of a child across the bar of two oceans, and the re-formation of that bar he regarded as certain—it would probably be re-formed beyond Port Said. He thought the Darien Canal would have a totally different success. The idea of forming this canal originated with Dr. Cullen, of Dublin. Nature, in scooping out the great gulf in which the West Indian islands lie, showed her determination to break through the Isthmus somewhere, and the great South Atlantic current would keep any canal open that was cut. The Americans thought that they would lower the temperature of Europe by removing so much of the Gulf Stream from us. But if their canal was one mile wide and 100 feet deep, they would take from us but $\frac{1}{1000}$ part of the heat we already possessed; and to make up this deficiency would cost the inhabitants of Dublin not more than *2s. 4d.* for additional fuel to each family—a sum they might well lose for the good of the whole race. The palæontological effects would not be of much interest in the case of either canals: a few Red Sea cockles might wander into the Mediterranean, and even this would not occur in the Darien Canal, as the same species of fish and molluscs were found on both sides of the Isthmus of Panama; and man must not forget that he has no power over nature.—The Rev. Maxwell Close read a paper "On some Corries, and their Rock Basins, in Co. Kerry."

Institution of Civil Engineers of Ireland, May 11.—John Bailey, C.E., in the chair. Mr. Alex. McDonald read a paper, "Notice of Le Chatelier's Counter-pressure Steam System." Professor Downing, LL.D., read "Notes on the Transport of Minerals by wire ropes." The author suggested the use of stationary wire rope, the mineral boxes to be pulled up by a common hempen rope, and to slide up the wire rope.

EDINBURGH

Royal Physical Society, April 27.—R. F. Logan, president, in the chair. Thomas Edmonston of Buness, Shetland, was elected a member of the society; and the Rev. Samuel Fraser, Melbourne, Australia, a corresponding member. The following communications were read to the meeting:—I. Our Pets in Unst, Shetland, by Thomas Edmonston of Buness, F.R.S.L. A vote of thanks was given to Mr. Edmonston for his interesting communication, notice being taken by Mr. Scott Skirving of the fact that the thanks of all naturalists were due to him as the preserver, on his estate in Shetland, of one of the few breeding places still remaining in Britain of the Great Skua Gull. II. Australian Entomology.—Notices of the Tarantula (Spider) and Hornet, by A. F. Grieve, Brisbane, Queensland. Communicated by D. Grieve. The President (Mr. Logan) said the insect called a hornet by Mr. Grieve was a species of *Pelopæus*, belonging to the family *Sphegidæ*; it was probably *P. lactus*. The habit of this genus is to store up spiders in mud cells, but surely it could not do this with the immense *sleygale*, which Mr. Grieve had also described. III. (1.) On the Skull of the Ringed Seal (*Pagomys fœtidus*, Gray), with special remarks on the osteological characters of the lower jaw. By James M'Bain, M.D., R.N. (2.) Notice of Clay Nodules, found at a depth of 292 feet in boring for an Artesian Well at Umballah, in India. By Thomas Login, C.E., F.R.S.E. Communicated by James M'Bain, M.D., R.N. IV. (1.) Note of a saline incrustation sold by the natives at Old Calabar, Africa. (Specimens sent to Dr. Smith by the Rev. Dr. Robb were exhibited.) (2.) Ornithological notes. (Specimens exhibited.) (3.) Notice of the capture of the Spiny Lobster (*Palinurus vulgaris*) on the west coast of Scotland. (Specimen exhibited.) (4.) Note of the capture of the *Seymnus borealis*, the Greenland shark, in the Frith of Forth. By John Alexander Smith, M.D. V. Notes of various species of *Crustacea* from Shetland, Caithness, &c. By C. W. Peach. (Specimens exhibited.)

Botanical Society, April 14.—Sir Walter Elliot, president, in the chair. The following communications were read:—On the Flowering and Fruiting of *Aucuba Japonica*, by Mr. P. S. Robertson. The author had observed that recently-introduced female plants from Japan (grown in a cold pit) came into flower in January and February, while the male plants, grown in the same circumstances, never came into flower till the middle of March. Yet he had every year obtained a crop of young seedlings from the berries, although the female flowers were quite shrivelled before the male ones expanded. He found that the common spotted variety, long grown in this country, does not flower till May or June, although grown in the pit or house with the others, and begins to expand its flowers when the males are getting past; yet it also never fails to produce a crop of fruit with perfect seeds. He thought that the pollen must lodge for some time in the scales of the unopened flower-buds, or must reach the pistils before the flowers are expanded; but how to account for the fertilising of the early flowering varieties, he was at a loss. This year he has forced on the flowering of the male plants by placing them in strong heat, and has all the varieties of the male and female plants in full flower at very nearly the same time, and accordingly he anticipates a much larger produce of berries than in former years, when they were left to the ordinary course. He exhibited a branch bearing berries with perfect seed; yet when that plant came into flower, there had not been a male plant in the house where it grew for fully a month previously. Mr. Sadler stated that he had been informed by the Messrs. Lawson that when there was a great lapse of time between the flowering of male and female Aucuba plants, they frequently collected the pollen and kept it wrapped in paper until such time as the female flowers were ready for fertilisation, when it was applied to the stigmas, and thus secured invariably a crop of fruit with perfect seeds. By grafting the male plant on the female, the two kinds of flowers might expand nearly at the same time.—"Remarks on *Grimmia pruinosa* (Wilson's MSS.)." By Mr. William Bell.—"Remarks on *Bœhmeria nivea* (*Urtica nivea* of Linnæus)." By Mr. Sadler.—"Memorandum on Ipecacuanha." By Mr. Clements R. Markham.—"Report on the Open-air Vegetation at the Royal Botanic Garden." By Mr. M'Nab.—"Remarks on the Embryos of the White Water-Lily (*Nymphœa alba*), and the Date Palm (*Phœnix dactylifera*)." By Professor Dickson.

Paris

Academy of Sciences, May 9.—The following mathematical papers were read:—"Some results obtained by the infinitely small displacement of an algebraical surface," by M. A. Mannheim, presented by M. Chasles; "On the division of hyperelliptical functions," by M. C. Jordan; and "On the existence of new classes, each containing an unlimited number of plane algebraical curves, the arcs of which present an exact representation of the elliptical functions of the first kind," by M. Allibert.—MM. Croullebois presented a reply to the remarks of M. Jamin, on the index of refraction of water.—A note, by M. G. Guéroult, on harmonic and melodic intervals, was presented by M. H. Sainte-Claire Deville.—A memoir, by M. C. A. Valson, on molecular actions, based on the theory of capillary action, was also presented by M. H. Sainte-Claire Deville.—M. C. Sainte-Claire Deville presented a note by M. E. Renou, on the latent heat of ice, in reply to M. Jamin's note, read at the last meeting.—M. Fizeau called the attention of the Academy to some errors which, he thought, had slipped into a communication by Father Secchi.—M. Regnault presented, in the name of M. Pfaundler, a claim of priority in the method employed by M. Jamin for the determination of specific heats.—M. Delaunay presented a note on the sun's spots, by M. Sonrel, in which the author called attention to some photographs exhibited by him, by which the perturbations of the surface of the sun are shown to have been lately remarkably active; a note, by M. H. Tarry, indicating the chief points of M. Respighi's theory of scintillation; and a second note, by the same author, on showers of dust and blood-rains. The author ascribed these phenomena to the action of cyclones upon the desert of Sahara.—MM. A. W. Hofmann and O. Olshausen communicated a memoir on the isomers of the cyanuric ethers.—M. Wade communicated a note confirmatory of M. Duchemin's remarks on the destruction of carp by toads; he referred to toads found fixed upon pike. M. d'Esterno remarked that the toads thus found attached to fishes were all males, and that this attack took place only at the breeding-time of the toads.—M. C. Robin presented a note by MM. Legros and Onimus, on the choreimorphic movements of the dog; and M. Balard communicated an extract of a letter from M. Castelhaz, on the employment of bromide of sodium, instead of bromide of potassium, as a medicine. The following papers were also read:—"A memoir on solids subjected to flexion," by M. L. Aubert; and "A note on the preparation of optically neutral sugar," by M. Maumené.

Vienna

Imperial Academy of Sciences, April 7.—Prof. Barth presented a memoir on isomeric cresoles.—Dr. Boué made some propositions for the purpose of getting rid of the ignorance which prevails as to the intellectual doings of certain foreign nationalities. He suggested that the transactions of academies established in certain places should be accompanied by translations or abstracts in French, German, or English.—M. G. Tschermak presented a memoir containing the results of an investigation of the meteorite of Lodran, near Mooltan, which fell on the 1st October, 1868, with a notice of a specimen of meteoric iron presented to the Mineralogical Museum, from the desert of Atacama.—A memoir, having the title of *Formicidæ neogranadenses*, by Dr. Gustave Mayr, was read, containing an account of the species of ants found in New Granada, and referring especially to those forms which throw light upon the affinities of the Formicidæ.—Dr. E. Reitlinger communicated the results of an investigation upon the spectra of negative electrodes, and of Geissler's tubes which have been long in use, which he had carried on in conjunction with Prof. M. Kuhn. The observers compared the spectra of the negative electrodes in Geissler's tubes with nitrogen, hydrogen, and oxygen, with those of the other parts of the tube, and found them to differ. To Wüllner's observations on the production of a new spectrum in hydrogen tubes after long use, the observers added similar results with nitrogen tubes. The fluorescence of the glass extends in these tubes to other parts than those immediately around the negative pole.—M. F. Unferdinger presented a memoir on the transformation and determination of the integral

$$\iiint F\left(\frac{x^2}{a^2}-\frac{y^2}{b^2}-\frac{z^2}{c^2},\ \alpha x+\beta y+\gamma z\right) dx\, dy\, dz$$

—Prof. Biesiadecki presented some investigations upon vesicle-formation and regeneration of the epithelium in the swimming membrane of the frog.—The report of the Central Observatory for meteorology and terrestrial magnetism for the month of March was communicated to the meeting.

April 21.—A memoir was read on some Pleuronectidæ, Salmonidæ, Gadoidæ, and Blennidæ, from Decastris Bay and Viti Levo, by Dr. F. Steindachner and the late Prof. R. Kener. Also one on the solution of dead organic matters, and one on the process of development and the structure of the walls of woody fibre, by D. T. Hartig, and one on the construction of a conic section, when this is defined by imaginary points and tangents.—Dr. Fitzinger presented the first part of his critical revision of the true Bats (*Vespertiliones*), containing the genera *Diclidurus*, *Taphozous*, *Saccolimus*, *Emballonura*, *Uroccyptus*, *Mystacina*, *Centronycteris*, *Saccopteryx*, and *Mosia*.—Dr. Horwath presented a paper on the production of inanition in animals by deprivation of heat.

April 28.—The following memoirs were read:—On the fish fauna of the Senegal (conclusion), by Dr. F. Steindachner; on the perfecting of involutions of high orders, by Dr. Emil Weyr; and on the determination of the sum of the angles of plane polygons, by M. A. Steinhausen.—M. von Haidinger reported upon some new observations relating to meteorites.—Dr. Boué again referred to his suggestion that the academies of northern and eastern Europe should furnish translations or abstracts of their memoirs in one of the three most familiar European languages.—Dr. T. Oppolzer presented a memoir on the transit of Venus in the year 1874.

New Zealand

Wellington Philosophical Society, January 29.—Annual meeting, Mr. J. C. Crawford in the chair. The election of the following office-bearers for the year took place, viz.:—President—Hon. W. B. D. Mantell, F.G.S. Vice-Presidents—J. C. Crawford, F.G.S.; R. Pharazyn, F.R.G.S. Council—W. T. L. Travers, F.L.S.; James Hector, M.D., F.R.S.; J. Kebbel; Wm. Lyon, F.G.S.; W. L. Buller, F.L.S.

Dr. Knox then gave a description of a specimen of *Bernardius Arnuxii*, which had been recently captured in the harbour, and the most important parts of the skeleton of which he had secured for the Museum. The animal was evidently full grown, and measured thirty-three feet, and what he desired to draw special attention to was the fact that while it presented well-developed teeth, yet they did not project through the gums, but were included in a deep socket with the tip covered in by thick fleshy gums. The use of such teeth, he considered, must be limited to the stimulation of the salivary glands by a reflex nervous process, as they could neither seize, divide nor masticate the food of the whale. Messrs. Mantell and Travers both considered that the teeth exhibited marks of the attachment of the gum round a projecting point of polished enamel, and that the teeth were probably enclosed in the retractile sheath of the gum. Dr. Hector stated that, in a recent description by Dr. Haast of a whale of the same species, it was stated to have shown its teeth when infuriated, which supported the view that the teeth were not completely undeveloped externally.—The next communication by Dr. Hector, on the interior of the North Island, gave the leading features of the geology of the Kaimanawa and Ruahine ranges, which had been recently examined by him. The modern tertiary rocks that form the eastern portion of the Hawke's Bay province, were described as rising in the interior to an altitude of 2,700 feet, but that it was probable that the Kaimanawa range and certain parts of the Ruahine mountains had always remained as islands above the tertiary sea. The tertiary rocks comprise three groups—1. Limestone containing a large percentage of existing shells; 2. Clay marls, containing few shells; and 3. Sandstones and conglomerates with irregular seams of coal, some of which might yet prove valuable as fuel. The upper group is of much later date than the others, but all are distinctly tertiary. The axis of slate rocks, which divided the tertiary series at the time of the development of the conglomerates, is within twenty miles of the present East Coast line, but is broken through by several modern rivers which rise in the Taupo plains; so that easy passes exist from Napier to the interior, a circumstance which has an important bearing on the opening up of the country. The Kaimanawa range is formed of the same slate and sandstone rocks as the Ruahine, but it lies at a considerable distance to the west of the proper axis of the island. The space left between them is occupied by the same tertiary rocks as on the east side, and which slope gradually to the sea-coast at Wanganui. As the tertiary rocks are quite free from any trace of volcanic matter, the eruption of the central volcanoes must have commenced after their deposit was completed. In referring to the auriferous specimens which had been found on Mr. Lyon's run at Kereru, Dr. Hector stated that chemical analysis had proved that, notwithstanding its granitic appearance, the rock to which the gold quartz was attached was only an altered form of the sandstone, as it contained traces of graphite, and 91 per cent. of silica. This is strongly in favour of the view that it is derived from the Ruahine range, as the sandstones in them have been previously mistaken for granite. After alluding to the recent increase in the activity of the volcanic forces in the Tongariro district, Dr. Hector described the route to the West Coast from the interior, and drew attention to maps and reports by Mr. Geo. Swainson and Mr. Field. He also exhibited a new geological map of the central district. The Hon. Mr. Fox considered that there was no doubt of the practicability of a route to Taupo district from the Wanganui coast. He believed that the track through the bush country was almost completed, and he was glad to find that no insurmountable obstruction would be encountered beyond that point. In reply to Mr. Mantell, Dr. Hector stated that he did not think that any rich auriferous quartz had been obtained in the Kaimanawa, but that his opinion remained unchanged as to the probability that gold would yet be met with in the district he had described.

PHILADELPHIA

American Philosophical Society, March 4.—A paper was read entitled "On the Periods of certain Meteoric Rings," by Prof. Daniel Kirkwood. Mr. P. E. Chase discussed the subject of the tides, referring to the recently-published theory of Prof. Challis, and contrasting his views with those of Airy and others. Prof. Cope read a paper "On *Adocus*, a genus of Cretaceous Emydidæ." Dr. Brinton read a paper entitled "Contributions to a grammar of the Muskokec language."

March 18.—Prof. Cope described the disinterment of a number of human remains from a pit in New Jersey, which probably belonged to some of the first European emigrants, whose history has not been preserved. He also exhibited photographs of human foot-tracks, sculptured in Cretaceous rocks of Kansas, and made observations on vertebræ of a large gavial from New Jersey. Dr. Brinton made some observations on a dictionary of the Maya language.

April 1.—Dr. F. V. Hayden described the position and appearance of the Tertiary strata on Green River, Wyoming Territory, mentioning the highly bituminous character of the shales. Prof. Cope exhibited two species of fishes from them, which he regarded as new, and named *Cyprinodon levatus*, and *Clupea pusilla*, and stated that their presence indicated connection with tide-water. Dr. Hayden mentioned the occurrence of insects and Myriopoda in the same shales.

DIARY

THURSDAY, MAY 19.

ROYAL SOCIETY, at 8.30.—Experiments on the Use of Alcohol (ethyl alcohol) in the Human Body: Dr. Parkes and Count C. Wollowicz.—On the Cause and Theoretic Value of the Resistance of Flexure in Beams subjected to Transverse Stress: Mr. W. H. Barlow.—On Deep-sea Thermometers: Commander J. E. Davis, R.N.—On the Difference between a Hand and a Foot, as shown by their Flexor Tendons: Rev. Dr. Haughton, and other papers.

SOCIETY OF ANTIQUARIES, at 8.30.—On recent discoveries in the Roman Wall, comprising Eighteen inscribed Altars: Rev. C. J. Bruce.

CHEMICAL SOCIETY, at 8.—On some Bromine Derivatives of Coumarine: W. H. Perkin, F.R.S.

ANTHROPOLOGICAL SOCIETY, at 8 (at St. James's Hall).—Race in Music: Henry F. Chorley.

ROYAL INSTITUTION, at 3.—Electricity: Prof. Tyndall.

FRIDAY, MAY 20.

ROYAL INSTITUTION, at 8.—Atoms: Prof. Williamson.

SATURDAY, MAY 21.

ROYAL INSTITUTION, at 3.—Comets: Prof. Grant.

MONDAY, MAY 23.

ROYAL GEOGRAPHICAL SOCIETY, at 1.—(Anniversary Meeting.)
VICTORIA INSTITUTE, at 4.—(Anniversary Meeting.)
LONDON INSTITUTION, at 4.—Botany: Prof. Balfour.

TUESDAY, MAY 24.

LINNEAN, at 3.—(Anniversary Meeting.)
ETHNOLOGICAL SOCIETY, at 4.—(Anniversary Meeting.)
INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion on Hot Blast Stoves.—On the Relative Safety of different Methods of Working Coal: George Fowler.—On Coal Mining in Deep Workings: Mr. Emerson Bainbridge, Stud. Inst. C.E.

WEDNESDAY, MAY 25.

GEOLOGICAL SOCIETY, at 8.

THURSDAY, MAY 26.

SOCIETY OF ANTIQUARIES, at 8.30.

ZOOLOGICAL SOCIETY, at 8.30.—On Dinornis (Part XVI.), containing Notices of Internal Organs of some Species, with a Description of the Brain and some Nerves and Muscles of the Head of the Apteryx australis: Professor Owen, F.R.S.—Notes on the Anatomy of the Prongbuck (Antilocapra americana): Dr. J. Murie.—Some Remarks on the Poison Glands of the Genus Callophis: Dr. A. B. Meyer.—Notes on some Fishes from the Western Coast of India: Surgeon Francis Day.

ROYAL INSTITUTION, at 3.—Electricity: Prof. Tyndall.

BOOKS RECEIVED

ENGLISH.—Balfour's Class Book of Botany, 3rd Edition (A. and C. Black).—Meteorology: Sir J. F. W. Herschel (A. and C. Black).—How Crops feed: S. W. Johnson (Trübner and Co.).—Lecture Notes for Chemical Students, Vol. 1.; Inorganic Chemistry, by E. Frankland (Van Voorst).—Trowbridge's Annual of Scientific Discovery for 1870 (Trübner and Co.).—Stanford's Family Atlas; Stanford's Complete Atlas; Stanford's Cyclopædian Atlas (E. Stanford).—Mammalia: their various Orders and Habits, by L. Figuier (Chapman and Hall).—Researches into the Early History of Mankind, new edition, by E. B. Tylor (Murray).

FOREIGN (through Williams and Norgate).—Malacologia del Mar Rosso: A. THURSDAY, MAY 26, 1870

THE NEW NATURAL HISTORY MUSEUM

WITHIN the last few days two members of Her Majesty's Government, the Chancellor of the Exchequer and the Premier himself, have declared, in their places in Parliament, that it is the wish and intention of the Ministry to carry into effect, without further delay, the long-talked-of project of erecting a special building to contain the Natural History Collections of the British Museum.

That this announcement will be received with great satisfaction by the large body of persons interested in the various branches of natural history in this country there can be no doubt, although there may be misgivings in some quarters lest the fullest advantage should not be taken of so grand an opportunity of making the very best museum of the kind in the world. These misgivings are in a great measure justified by the present condition of not only our own, but nearly all other European Zoological Museums, and more especially by the plans that have at various times been put forth in a semi-official manner, as representing the ideal of what such a museum should be.

Long and extensive experience has, or ought to have, taught us the best principle of construction as applied to libraries and picture galleries; but the natural history sciences are in their infancy as compared with literature and art, and the best methods by which their treasures can be housed and exhibited have yet to be learned. The way in which this is done in the new Museum will exercise so great an influence upon the progress of these sciences, that it should not be determined upon without full consideration by those who are most conversant with their present state, and with the probable wants of a future generation of students.

Let the reader imagine what a public library would be if the books, instead of being shut up and arranged on the shelves for consultation when required, had every single page framed and glazed and hung on the wall, so that the humblest visitor as he passes along the galleries has only to open his eyes and revel in the wealth of literature of all ages and all countries, without so much as applying to a custodian or opening a case. There is something truly heroic in the conception of such a scheme; but laying aside all questions of space and cost, what would be its real utility to those who are able to appreciate and make true use of its contents! All the inconveniences, all the impossibilities, I may say, of a library arranged upon such a plan would be found in a museum containing anything like an adequate number of objects for the purposes of really enlarging the boundaries of scientific zoology, in which every specimen contained in it were exposed to the gaze of all who choose to enter its walls.

We are only beginning to form any idea of the enormous numbers of specimens actually required to enable us to rest our generalisations relating to most zoological problems upon a firm basis, and of the importance of keeping these specimens in such a condition, and so placed, that they can be examined and compared with the greatest facility. Provision should, therefore, be made in the new Museum for the great bulk of the collection being thus treated. It would be quite a mistake to suppose that they would then be shut up and put away, and that the public have no further concern in them, and ought not to be expected to pay for their accommodation. They would be in exactly the same circumstances as the books in a well-arranged library, and ought to be equally accessible under suitable regulations; and there are thousands of people who will read with interest the conclusions that scientific men will draw from their study of them, who would never care to see, or if they did, never learn anything from, the specimens themselves.

At the same time, the other essential function of a Natural History Museum, the diffusion of knowledge among the general public, should be carefully provided for, and means should be taken by which these two objects may be carried on simultaneously, and, at all times, without interfering with each other, instead of continuing the present excessively inconvenient system of alternate closed and open days. This, and many other advantages, upon which I need not dwell at present, can be readily secured by the admirable plan, first suggested, I believe, by Mr. Sclater, of having all the glass-cases hermetically closed on the side towards the public galleries, and opening behind into the working-rooms in which the unexhibited portions of the same series are arranged in drawers or cabinets. In this way, any exhibited specimen, if required for examination or comparison, could be readily removed and replaced, without inconvenience to the visitors, and without letting in the dust which necessarily fills the air of the crowded public galleries. One of the principal objections to lighting the Museum with gas in the evening would also be obviated if this were carried out.

Another important requirement in the arrangement of a new Museum of Natural History is the abolition of the special department of palæontology. There might be a comparatively small *geological* series, consisting of characteristic fossils arranged stratigraphically, but the great bulk of extinct animals should be incorporated with the zoological series, so that they may be studied side by side with their existing representatives, not only by the sight-seeing public and specially-instructed visitors, but also by those who have charge of the collections. If the construction of the new museum tends to perpetuate the present artificial distinction between extinct and recent species of animals, it will hinder instead of promoting the progress of any general conception of the organic world as a whole, and will also impose unnecessary difficulties in working out the minute comparisons by which the affinities and gradations between the various units of which that world is composed are recognised.

It would probably be premature at the present time to enter into any further discussion of details, since the subject has so often seemed nearly as far advanced as now, and has as often receded again into the far-off distance. But after the declaration of last Friday evening it should be in a fairer way of being realised than ever before it, and it behoves the working naturalists of the country to lend their aid in furthering the excellent intentions of the Government by making known their well-considered opinions upon this most important question.

W. H. FLOWER

ON THE EXTRACT OF MEAT

AN article of food has lately been introduced which has found its way into every grocer's and chemist's shop in the country, and for which there is in all parts of the world a vast demand. This substance is variously called the Extract of Meat, the Juice of Flesh, Liebig's Extract, and in Latin, *Extractum Carnis Liebigii.* The name of Baron Liebig, the great chemist, is more especially connected with this compound, as he has undoubtedly the merit of having first called attention to it as a valuable article of diet. In his "Familiar Letters on Chemistry," he devotes a letter to vegetable and animal food, and gives an account of their various chemical components. He shows with regard to all animal flesh, that besides fibrine, albumen, gelatine, and fat, it contains certain other constituents which may be separated from these by a simple process of infusion, straining, and evaporation. The substance thus obtained is the extract of flesh. This compound was known to chemists previous to the researches of Liebig, and he especially mentions those sagacious and experienced physicians, Parmentier and Proust, who had long ago endeavoured to introduce a general use of the extract of meat. They, however, regarded it as a remedy for disease and exhaustion, and recommended it as a resource for the diseased and wounded soldier on the field of battle or in camp. "In the supplies of a body of troops," says Parmentier, "extract of meat would to the severely wounded soldier be a means of invigoration, which with a little wine would instantly restore his powers, exhausted by great loss of blood, and enable him to bear being transported to the nearest field hospital." "We cannot," says Proust, "imagine a more fortunate application. What more invigorating remedy, what more powerfully acting panacea than a genuine extract of meat dissolved in a glass of noble wine? Ought we then to have nothing in our field hospitals for the unfortunate soldier whose fate condemns him to suffer for our benefit the horrors of a long death-struggle amidst snow and the mud of swamps?" That which these sagacious physicians recommended for dying soldiers is now a common article of daily consumption in the households of Europe. That which was amply demonstrated to be of use to the dying soldier, was found no less adapted to restore the vital powers of the poor in our hospitals, and that which proved of benefit to the exhausted nervous powers of the poor was soon found to be of value to the exhausted nervous powers of the rich. The doctor, from prescribing it to the poor in hospitals, learned to prescribe it to his patients among the rich. The result of the action of this substance on exhausted nervous systems and debilitated frames is no delusion, it is no influence of imagination, no simple belief in doses without power, but a real experience which is accumulating from day to day, and making demands on the manufacturers of this all-potent juice, which their utmost industry cannot meet.

Let us now inquire how this is. To the unlearned there is a ready reply: the extract of flesh is all the nutritive power of flesh concentrated, and if one pound of juice is got from thirty pounds of flesh it must be thirty times as nutritious. But it is not so, and it will be surprising to those who believe in this doctrine to hear that the extract of meat contains little or nothing of what may be said to be nutritious at all. The substances which go to form nourishment for the body, which are contained in meat, are fibrine, albumen, and fat, but these are not present in the extract of meat.

One hundred parts of beef contain the following constituents:—

1. Fibrine	4
2. Albumen	4
3. Gelatine	7
4. Fat	30
5. Mineral matters	5
6. Water	50
	100

Let us contrast with this the composition of a hundred parts of Liebig's Extract of Meat:—

1. Creatine, Creatinine, Inosic Acid, Osmazome, &c.	51
2. Gelatine	8
3. Albumen	3
4. Mineral matters	21
5. Water	17
	100

The difference will be seen at a glance. The water has diminished by half, the albumen is less, and there is four times the quantity of mineral matter, and a set of bodies is introduced which occupy half the bulk of the compound, which are not noticed in the composition of beef at all. If, then, the Extract of Meat differs from beef and from all other nutritious articles of diet, it is not in containing nutritious matters, but in containing the chemical compounds just mentioned in large quantities, and mineral matters. It is to these, then, we must look for the explanation of the marvellous powers which the extract of flesh exerts on the human system.

What, then, are the creatine, and its associates creatinine, inosric acid, &c? All we know of creatine is that it is a crystallisable body, and that it has an alkaline action, and is capable of combining with acids to form salts. In this respect it is like quinine, morphine, strychnine, and other substances from the vegetable kingdom capable of exerting a great influence on the nervous system. It seems to stand between these latter bodies and theine, which is contained in tea and coffee, and which has not the power of combining with acids. Whatever may be its chemical character, we know little of its action on the human body. It is easily resolvable into urea, and seems to be one of those compounds which are the result of the decomposition of albumen and fibrine into nerves and muscles before these are ultimately removed from the body. Whatever may be the true chemical or physiological relations of creatine, we cannot but regard the presence of this substance in the extract of flesh as playing an important part in the action of the latter on the human system.

When creatine is boiled with mineral acids another product results, which differs from creatine, and is called creatinine. This again may be decomposed, and forms sarkosine. The special action of these substances on the animal system is unknown, but we know they are contained in the juice of flesh. Besides these substances, there is inosic acid, and inosite, or muscle sugar, found in the juice of flesh, and probably there are other compounds not yet made out, and of whose special action on animal organisms we as yet know nothing. But although our knowledge of the action of these things is very imperfect, there is one thing we know, and that is, that the albumen, the fibrine, the fat, and the gelatine, will none of them act separately or together, as they do when combined with the juice of flesh.

Many experiments have been performed in France, Belgium, and Germany, which show that fibrine alone will not support life, that albumen alone (as in white of eggs) will not support life, that gelatine alone will not support life; we are thus driven to the conclusion, seeing that all these substances are easily digested and appropriated when combined with the juice of flesh, that the alkaline and other substances referred to perform a most important part, if not in ultimate nutrition, at least in the previous process of digesting food.

If we study a little our individual experience in the matter of digestion, we may find perhaps an approximate solution of the mode in which Liebig's Extract acts in giving strength to the weak, and new life to the exhausted. If we are hungry and eat dry bread the appetite soon palls, and we give up the effort; if we take some cold water we can consume more of the bread, and even with warm water, especially if flavoured with tea and sugar, still more. The latter evidently acts as an incentive. If we add salt to the water the same effect is produced. But if we now take a basin of soup—for soup is but a solution of the juice of flesh—we shall find that we can take into our stomachs with relish four or five times the bread we could have eaten dry or with cold water. How is this? We are all aware of the fact without being able to give the explanation. It is evident that an effect has been produced upon the nerves of the stomach and its glandular apparatus, which has enabled it to digest and deal with food which before was a mere inanimate burden in its cavity. If the nervous system is excessively exhausted or unable to act, as it is sometimes in disease, the glass of "noble wine" recommended by Proust will increase the effect upon the paralysed nerves. It is in this way, it appears to me, that the extract of flesh taken with food acts in so beneficial a manner, as compared with tea, coffee, cocoa, beer, wine, or spirits. All these, whilst stimulating the nerves of the stomach to higher action, are attended with subsequent depressing and sedative effects, of which we see no sign in the action of a dilute solution of the juice of flesh.

There does not appear to exist any evidence of the subsequent beneficial action of the organic substances found in the Extract of Meat. Not that this ought to be denied to them. They may, like theine and quinine, supply more readily materials for the manufacture of working muscle and nerve than can be readily obtained otherwise than from the blood. The theory that these salts assist in nourishing the nerves has recently been put forward, with his accustomed ingenuity, by Professor Agassiz; and as the flesh of fish is known to contain more creatine than that of other animals, he recommends a diet of fish as especially adapted for the food of philosophers and those who work much with their brains.

But whatever doubts may arise as to the action of creatine and its consequences on the ultimate nutrition of the nerves and muscles, there can be no doubt of the beneficial action of the mineral matters contained in Liebig's Extract. We eat salt because we do not get enough in our ordinary food. Besides salt, which contains chloride and sodium, we require other elements in our bodies. We require phosphorus, calcium, potassium, sulphur, and iron. Now, we do not add these artificially to our food as we do the chloride of sodium, and yet in our ordinary system of cooking and feeding we may deprive our bodies of these necessary elements. In soup we supply them, and they are contained in the juice of flesh. Whilst one hundred pounds of beef contain five pounds of mineral matters, one hundred pounds of Liebig's Extract contain twenty-one pounds of the same substances. Above seventy per cent. of these consist of phosphorus and potassium, whilst the remainder consists of lime, iron, sulphur, and magnesia. Here then, perhaps, we may find a nutritive action for the Extract in supplying those elements to the nerves and muscles which are constantly being removed by the changes of composition in the tissues, through the vital activity of the body.

From the above statement it will be seen that the juice of flesh presents after its manufacture no new product, but that it contains the same constituents that are ordinarily met with in the flesh of animals. The great advantage that it confers is that it is already fit for use. A teaspoonful of the Extract in a pint of hot water is a stock for any kind of soup, and may be prepared in a few minutes. To this may be added bread, potatoes, vegetables, eggs, meat, or flavouring essences of any kind, and the most agreeable of soups can be thus prepared. Its use in this direction is not confined to the sick-room; it may be used economically for the daily manufacture of soup for the table, and where the speedy preparation of hot food is desirable there is nothing to equal it. For the dyspeptic, and those whose stomachs have become paralysed by the use of theine in tea and coffee, it quickly restores the digestive powers; and for a permanent beverage, morning and evening, it is better than tea or coffee. Of course, this solution should always be taken warm, although after cooling it is perfectly thin, and is not like soup made from meat, which becomes thick on cooling, an effect due to the gelatine, and greasy, from the fat floating on the surface.

The Extract is sold for ten or twelve shillings a pound, and a pound of Extract represents thirty pounds of lean beef. It is therefore no economy to make it and sell it at this price in England; but as it can be made in South America and Australia, where cattle and sheep are in abundance, even at the low price of ten shillings a pound, including carriage, a large profit is made. Within the last few years an establishment has been erected at Frey Bentos, in South America, for the manufacture of this Extract from the wild cattle of that part of the world. There are also two distinct manufactories on the Clarence, New South Wales. These places are worked by companies which supply immense quantities for public use. There are also private manufactories in many parts of America and Europe, and one in Scotland, supplying the same substance. As far as published analyses have gone, the Extract has the same general composition, and on that account one is not to be preferred above another. But there is a difference in flavour, and that which is preferred in that point will fetch the highest price and have the largest sale. Here, as in all other kinds of food, it is the flavour that makes the quality. It is the *bouquet* of wine and not the alcohol that constitutes its value.

E. LANKESTER

THE SNAKES OF AUSTRALIA

The Snakes of Australia: an Illustrated and Descriptive Catalogue of all the known Species. By Gerard Krefft, F.L.S., C.M.Z.S., &c., &c., Curator and Secretary of the Australian Museum. Large 8vo. pp. 100, with 12 lithographic plates. (Sydney, 1869. London: Trübner and Co.)

WHEN we consider how very small is the number of zoologists who take an interest in, or make a special study of, the animals of the class Reptilia, and how little attraction this branch of zoology appears likely to have for the public, we cannot but feel surprised when, now and then, one bolder than his fellow-labourers prepares a comprehensive account of some portion of these animals, and ventures to put it forth in the shape of a goodly volume, which must have cost the author a vast amount of unappreciated labour, and the publisher a round sum of money without a prospect of its speedy return. Thus, on examining the work which has just been published under the above title by the Curator of the Sydney Museum, we find that the investigations on which it is based have been carried out by fourteen zoologists only, of whom not more than one half belong to the present generation, whilst the other half have only described a species or two incidentally.

The causes of this neglect of the study of reptiles are obvious. In Europe, a boy whom Nature has endowed with a taste for contemplating her works, begins to collect the objects most accessible in his neighbourhood, and most attractive by their variety of form or colour; he collects, and perhaps studies, birds and their eggs, beetles, butterflies, shells, or plants. What is more natural than that he should continue to devote himself to the same particular branch, if the duties of more mature years allow him to develop the fancy of his boyhood into scientific research? Consequently, ornithology, entomology, conchology, and botany are *popular* pursuits.

There are but few who become connected with public collections, and who, from more expanded views or duty, enter into the study of animals which have but rarely formed part of private collections. A boy in England would soon get tired of his taste for natural history, if he had to develop it through the scanty means afforded by the small number of British reptiles; and Ireland, as far as we are aware, has not yet produced a single herpetologist (although, as Mr. Krefft informs us, that island is inhabited by snakes—a fact which is certainly new to us).

On the other hand, we may predict that herpetology will become a more popular science in Australia, where reptilian life abounds. Snakes must be numerous there, for we are told that, "from six to ten specimens, belonging to different species, were captured some years ago under a single stone not many miles from the city of Sydney;" that, "to go snake-hunting has been a pastime with school-boys for years," and that "the collecting-bag often forms part of the outfit of the wallaby-hunters, by whom the old sport of boyhood is not forgotten." Snakes in Australia must also play quite as important a part in relation to mankind as in tropical countries; for not less than two-thirds of the species, and fully nine-tenths of the individuals, are venomous. Ten years ago only some forty species of Australian snakes were known; and it is chiefly due to the energy of Mr. Krefft, as collector and curator of the Australian Museum, that this number is now doubled.

The work begins with a copious introduction, in which the natural history of snakes generally is treated in a popular manner; then follow technical descriptions of the eighty species known, and their geographical distribution and habits are indicated, the volume being illustrated by twelve lithographic plates. The descriptions are chiefly reproductions of the original diagnoses given by the various authors; and we do not notice any species which has not been described elsewhere. Thus, whilst we bear witness to the great progress in Australian herpetology due to Mr. Krefft's labours, we must add that he has effected it previously to and independently of the publication of his book. But, like all conscientious compilations, it will be useful to the student, and will supply a real want among residents in Australia desirous of acquainting themselves with objects which daily come under their notice.

Great credit is likewise due to Mr. Krefft for the caution used in working up his materials. European collections contain by far the greatest number of the typical specimens of the species described within the last century; and men working at a distance from this principal source of information, and more or less dependent on descriptions, are only too much exposed to the risk of failing in the determination of species, applying old names to really new species, and describing old ones as new. No end of labour in rectifying these errors is caused to European naturalists by such premature publications. But Mr. Krefft has been for years in constant communication with his fellow-labourers in England and Germany, sending duplicate examples for identification; and thus creating a well-determined collection, he has laid a solid basis for his own future researches and for the instruction of Australian students. We have heard an authority on the subject express the belief that there is not in the book a single species erroneously determined.

The plates which accompany the volume are the work of two ladies, Miss Scott and Mrs. Edward Ford, who, considering the peculiar difficulty of drawing snakes, have accomplished their task extremely well.

In conclusion, we must congratulate the trustees of the Sydney Museum on having found so able and zealous a curator as Mr. Krefft; and express the hope that his book may lead to new discoveries sufficiently numerous to call for a second edition. It is a good sign that the scientific literature of our colonies already contains such books as the one under review. May the number soon be largely increased.

A. GUNTHER

OUR BOOK SHELF

The Bottom of the Sea. By L. Sonrel. Translated and Edited by Elihu Rich. Pp. 402, 67 Illustrations. (London: S. Low, Son and Co. 1870.)

WE cannot do better than quote part of the translator's preface, wherein he states that the book "bears the same relation to the strictly scientific treatment of the subject as a popular lecture on art to instruction in the studio; a ramble through a museum to a lecture on science; or a short pleasure-sail on the coast, with here and there an opening glimpse of the scenery," &c. M. Sonrel devotes the first portion of his book to submarine orography, with full explanations of deep-sea soundings, configuration of sea-bottom, submarine scenery, the various charts of the sea-bottom, and the like. The phenomenon of phosphorescence is explained; and the colour and temperature of the ocean are also dwelt on; next comes submarine life, with a long description of wonderful sponges, polypi, and corals. He relates, also, many legends with regard to marine monsters. Then we have man, and his work at the bottom of the sea, divers, diving apparatus, raising of ships, construction of bridges, submersion of towns, submarine volcanoes—all are graphically described. The last part is devoted to the action of rivers and currents on the sea-bottom, the dunes of Gascony, and villages buried beneath them. M. Sonrel lastly illustrates the insignificance of man compared with the ocean, by telegraphic cables, with an engraving of a fossilised cable. The following passage ends this interesting volume:—"If the intelligence of man has placed him at the head of the creation, the feeble influence that he can exercise over Nature ought to humble his pride. All that he can accomplish by physical labour is almost imperceptible by the side of the work effected by the microscopic infusoria; man, the giant, is dwarfed in results by the almost invisible atom!" This book is well illustrated throughout, and is admirably adapted to those who require light scientific reading.

Lehrbuch der Chemie für Land und Forstwirthe. Von S. J. Möser. Large 8vo., pp. x. and 355. (Vienna: Braumüller, 1870.)

IN this work, which was written for agricultural students, Dr. Möser has made it his aim to supplement the educational deficiencies under which his German pupils labour; and as the time which they can devote to purely chemical study is (he informs us) unduly limited, he brings into prominence in this manual only the more general and important facts, while the minor details, which are described in a smaller type, are kept somewhat in the background. The inorganic part is comprised in 183 pages, inclusive of an appendix, in which we are pleased to notice special sections devoted to the formation of saltpetre and the soil. The organic part contains 202 pages, and is consequently cut very short; but certain parts of it and its appendix are occupied very fully with physiological chemistry, and seem to have been ably executed,—perhaps more *con amore* than the rest of the *Lehrbuch.* Dr. Möser offers an apology for adopting the old notation; but we think his views on this subject are likely to alter with a new edition.

La Chambre Noire et le Microscope: Photomicrographie pratique. Par Jules Girard. (Paris: F. Savy. London: Williams and Norgate.)

THIS little volume contains a useful description of the apparatus required for photographic representation of microscopic objects, and a detailed account of the various operations involved in this art. It also describes the application of photomicrographic plates for lectures and educational purposes, by means of the oxyhydrogen light and the lantern. The book is illustrated with several well-executed woodcuts. A translation of it would be very useful to those engaged in this kind of work.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Oysters of the Chalk, and the Theory of Development

THE interesting notice, in your last number, of M. Coquand's "Oysters of the Chalk," draws inferences unfavourable to the Theory of Development or Evolution which scarcely seem warranted by the facts. It need not be "difficult to imagine the creature as existing under such conditions, that one species, while engaged in 'the struggle for existence,' should starve out and extinguish another;" for however widely we may find a fossil species dispersed, it is not probable that it occupied the whole of its territory at one and the same time, and in the limited area occupied immediately before its extinction, new varieties may have prevailed over and displaced the old by some slightly superior adaptation to the food-supply of the region. The extinction of any particular species may in some instances have been due to the extinction, or loss by other means, of its own appropriate food. Again, it is not necessary to suppose that the hinge, or the internal or external structure of the shell of an oyster, has been altered by what may be called the direct action of "Natural Selection," since by the well-established principle of "correlation" the variation in one part of an organism is nearly or quite certain to produce variations in other parts. "If any such change did occur," it is argued, "it must have been *per saltum*, since with these mollusks, numerous as they are, there are no forms that can fairly be recognised as transitional." But this appeal to the evidence of facts is somewhat premature. The immense difference pointed out between the geological records of England and France in regard to these very oysters of the chalk, leaves it perfectly open for us to suppose that even the comparatively full French record is itself exceedingly imperfect, and that the transitional forms have either not been preserved, or remain yet to be discovered. Mr. Darwin gives reasons for believing that when variation once begins it continues with some vigour; hence, between two settled widespread species connected genealogically together we might expect a large number of transitional varieties, each represented by only a few individuals, so that the whole number of these transitional forms might well be lost to the geological record.

Finally, the objection from the scarcity of oysters at the present day, compared with the great abundance of species in the past, does not really touch the theory of development, which is concerned to explain how species come into existence, not how they go out of it. That varieties, species, genera, have been superseded or extinguished, within longer or shorter periods, is a fact admitted on all hands. The general principle of natural selection will account for this in the rough, maintaining as it does, that fresh varieties, species, and genera better adapted to the surrounding circumstances have arisen, and by their superior adaptation, unavoidably ousted the older forms. Digging down into the records of history we find a time when the Romans were supreme in the civilised world; no two consecutive years of the interval present any remarkable divergence of the prevailing conditions, yet now we may say of that Roman supremacy in the civilised world, that, "like the Mastodon, it is a thing of the past." May it not be that both in races of men and every other race of creatures, there is a certain store of vitality and vigour, capable of very extensive and long-continued development, but capable also of exhaustion?

Torquay, May 14 THOMAS R. R. STEBBING

Euclid as a Text-book

THERE are many engaged in the work of education in this country, besides those who have come prominently forward in the matter, who feel strongly that Geometry as now taught falls far short of being that powerful means of education in the highest sense which it might easily be made. They find themselves, in the majority of cases, compelled to use in their classes a text-book which should long ago have become obsolete.

We have lately had instances in abundance of the power of combined action. If the leaders of the agitation for the reform of our geometrical teaching would organise an Anti-Euclid Association, I feel sure they would meet with considerable and daily-increasing support.

We of the rank and file do not feel strong enough to act alone, and yet think we might do something to help forward the good cause by co-operating with others.

The immediate objects of such an association should be in my opinion (1) To collect and distribute information connected with the subject; (2) To induce examining bodies to frame their questions in geometry without reference to any particular textbook.

RAWDON LEVETT

King Edward's School, Birmingham

Philology and Darwinism

MR. FARRAR'S interesting communication on this subject in a recent number of NATURE, suggests to me a few remarks. As one who has paid considerable attention to the various dialects existing throughout Scotland, as well as to the manner in which our Gaelic-speaking population is by stern necessity obliged to attempt the pronunciation of Anglo-Saxon words, I have become thoroughly convinced that the growth, life, and death of languages are subject to fixed laws. The Highlander whom I meet and who tells me this is a "Koot tay" is as unconsciously obeying Grimm's law of the transposition of consonants as the sun above him is obeying Newton's law of gravitation.

There is this difference, however, between Mr. Darwin's teachings regarding animals and the changes of language, that whereas those animals whose breeding and training are most subject to man's conscious action exhibit the greatest amount of variability, those dialects which are the most neglected and despised by educated men, and which, in this respect, may be called the weeds of speech, are far more variable than Queen's English, watched over as the latter is by such a host of schoolmasters, lexicons, and grammars. The difference of pronunciation of the same words in different counties is great, while many words in the dialect of one county are quite unknown in that of another, in this respect presenting a striking analogy to the Flora of the country. Even in words formed from sound, in which case, at first thought, we might expect considerable uniformity, the difference is often very marked, as between Scotland and England. The words imitative of the animal voice, or of the different cries of the same animal under different sensations are sometimes unlike, for the horse *neighs* and the cat *mews* in England, whereas they respectively *nicher* (*ch* guttural), and *nyioo* in Scotland. Sometimes the imitative word is from the sound of different organs, as *lapwing* in English from the flap of the wing; *peewit* in Scotland from the sound of the voice. Generally people so ignorant as to be necessitated always to express their thoughts in a rustic dialect, do so with the assistance of more or less gesture, and even this gesture is not quite whimsical, but has family and county resemblances. In conclusion, my impression is that the dialects which run wild are much more variable than those under man's care, which is the reverse of the case with wild and domestic animals and plants.

S. J.

Xanthidia in Flint

DR. CARPENTER, in his recent lecture at the Royal Institution on "the Temperature and Animal Life of the Deep Sea," speaks of the resemblance of the globigerina mud to chalk as being "greatly strengthened by the recognition of several characteristically cretaceous types among the foraminifera scattered through the mass of *globigerinæ*, of which it is principally composed; as also of the *Xanthidia* frequently presented in flint. (NATURE, vol. i., p. 564.)

The precise nature of the spinous orbicular bodies found in flint, and generally called *Xanthidia*, has hitherto been a matter of some doubt. Ehrenberg described them as fossil species of his genus of supposed polygastric animalculæ, *Xanthidium*. Their structure, however, differs in many respects from true *Xanthidia*, which form a genus of *Desmidieæ*, now universally admitted to be vegetable organisms, and, like nearly all desmids, having compressed bipartite cells, whilst the fossils have globose and entire cells. The most recent opinion has been that they are the fossil sporangia of other species of *Desmidieæ*, and they do indeed bear considerable resemblance to the sporangia of various species of the genera *Micrasterias*, *Euastrum*, *Staurastrum*, *Cosmarium*, and *Closterium*. An objection to this opinion arises from the fact that *Desmidieæ* are (so far at least as at present ascertained) exclusively fresh-water plants, and do not appear at all adapted for a deep-sea existence; whereas on the other hand, the chalk containing the flints may now be said to have been conclusively proved to have been formed at a considerable depth at the bottom of the sea: and the other organisms with which the fossils in question are found associated are undoubtedly marine.

The discovery of these *Xanthidia* (?) then, at an ocean depth of 767 fathoms, is a most important fact, whatever their nature may be; what that nature is, I, and I doubt not many others of your readers, would be glad to learn from Dr. Carpenter, or others who have had an opportunity of seeing the specimens he alludes to.

Winchester, May 14 FRED. J. WARNER

What is a Boulder?

WITH all terms in ordinary use there is a looseness of meaning, which, while not in the least degree inconvenient in common language, becomes so when transferred to the would-be-exact nomenclature of science.

Hobbes says, "A name is a word taken at pleasure to serve for a mark which may raise in our own mind a thought; like to some thought we had before, and which being pronounced to others may be to them a sign of what the speaker had or had not before in his mind."

It is obvious, however, that a name pronounced by a speaker, or written by an author, can only raise, in the minds of others, the proper thought, when the exact meaning of such a name has been agreed upon by those who make use of the name; and it appears to me desirable that in all cases when names in common use are transferred to the language of science, their exact meaning should be stated. In some sciences, as in botany, this is done, where such terms as leaf, stem, root, &c., are defined apart from their ordinary signification, but much remains to be done in this way. Thus, take the query at the head of this letter. I have tried to find out exactly what a boulder is, and I completely fail. According to Dance a boulder is "a mass of rock, whether rounded or not, which has been transported by natural agencies from its native bed." This definition is excellent at first sight, but it fails, as the term "mass of rock" conveys no clear idea as to size. Ask half-a-dozen persons the smallest size they would attribute to a mass of granite, and the answers would vary considerably. One cannot see why the smallest piece that would contain the constituents of the rock should not be called a mass, and in that case many of the large grains of sand on a granitic coast would be included in the term "boulder." But this is absurd, for we might then speak of carrying half a dozen boulders in the waistcoat pocket, or a geologist might suffer from having a boulder blown accidentally into his eye! There is apparently no determinate size at which a boulder begins or ends; but it seems to me desirable that some idea of size included should be given in the definition, and I would ask some of your readers to be good enough to state what they understand by a "boulder," with a view of getting an exact idea of the meaning of this frequently used term.

Midland Institute, May 9 C. J. WOODWARD

The Anglo-Saxon Conquest

A CORRESPONDENT, writing under the signature "A. Hall," in your issue of last week, suggests that in laying certain statistics as to the longevity of the Romano-Britons before the Royal Institution, I had "forgotten that the youth of Romano-Britain had for many generations been forcibly expatriated, drafted abroad to feed the armies of Imperial Rome." Your correspondent "appears to have forgotten" what the *résumé* of my lecture stated, viz., that my observations related to the time of Cerdic; and he will now no doubt recollect that a space of about three generations intervened between this period and the one to which he refers. Less than three generations is a sufficiently long period to allow of the balance which the Romano-British population is supposed to have suffered by being drafted into the Roman armies, righting itself.

I have, in a memoir which the Society of Antiquarians has honoured me by publishing in the "Archæologia" of this year, given other reasons, and these at greater length, for holding the explanation which your correspondent suggests for my statistics to be erroneous. I do not in that memoir quote, in illustration of and as a means of expressing that explanation, some lines from Mr. Henry Lushington's poem "Inkermann." These lines I did quote in my lecture, and will quote them here, as they may give pleasure to some of your readers. Speaking of the Russian slain, Mr. Lushington says:—

> Lay them there like soldiers—
> Men that did not blench.
> Many a sad serf-mother
> Yearns for these at home;
> Yet she thinks, "My children
> Never more shall come.
> Few, alas, of many
> Come back from the wars.
> There they die, fulfilling
> God's will and the Czar's!"

Oxford, May 23 G. ROLLESTON

Carp and Toads

IN reference to *Bufo calamita* attaching itself to the carp, and pressing its thumbs into the fish's eyes (see NATURE, May 12th), I would mention that the male Batrachia in the spawning season often attach themselves to any object, pressing the hands, on which is developed, at this season, a peculiar, black, wart-like structure, into the object which they seize—a stick, a human finger, or a carp as it appears, being sometimes hugged with spasmodic violence. A curious illustration of the reflex nature of this movement, and the inhibitory function of the cerebrum in regard to reflex actions, was witnessed by me lately, on cutting through the neck of a male toad. My finger was between the animal's fore legs, but on account of fright, or some other cerebral operation, no hugging action took place; but directly the connection between the spinal cord and cerebrum was severed, the arms joined closely upon my finger, the thumbs being pressed into it in the usual way, and the headless body held firmly to me with considerable muscular power. Just as the leg of the brainless frog is withdrawn more rapidly from acidulated water, than is that of a perfectly sound and healthy specimen, so did the hugging action of the forearms fail to be brought about by contact of the extremities with a foreign body whilst the animal was whole, but took place immediately upon the severance of the cerebrum from connection with the rest of the cerebro-spinal axis.

Hampstead, May 16 E. RAY LANKESTER

WITH reference to the disease existing amongst the carp at the Château de Montigny, and its presumed connection with "the first days of spring," and the animosity of the toad for the carp, permit me to take up the cudgels, not for the early spring but for the poor maligned toad, which like other possessors of jewelled heads has already but too many enemies. On two occasions I have noticed the curious train of symptoms detailed by M. Duchemin, commencing with blindness, and ending in death. One occurred in Norway, and the trout and grayling were the only fish affected; the other in Lord Bathurst's park in this town, when the pike only were attacked whilst the perch and tench escaped. In both these instances I instituted a series of experiments to ascertain the probable cause of death. No intestinal worms were discoverable, nor did any of the tissues appear congested or otherwise diseased, with the exception of the eyes, in which the cornea became opaque and friable so that on very slight pressure the crystalline lens escaped. The long duration of this blindness before death supervened, rendered it probable that starvation was at least usually the cause of death. In both cases spring was the time of the attack, but in neither were toads observed in proximity to the diseased fish; indeed, in that part of Norway where the disease existed, toads are almost unknown. One cause only has as yet suggested itself to me, and that is the presence of diffused mud in the water. As both in Norway and Cirencester, works had been undertaken, just previous to the outbreak of the disease, which had had the effect of introducing a large amount of clay into the water, and the "early days of spring" were so far implicated that they were days of rain and melting snow, and thus the products of degradation were added to the mischief caused by the hand of man.

Cirencester, May 14 W. D. CROTCH

Meteorological Phenomenon

ON the afternoon of Sunday, the 22nd, a very curious appearance was noticed by many. The sky was hazy, and the sun was seen through the haze of a pink colour, inclining to purple. I see by a newspaper that the same was noticed at Dublin. A red or orange sun is common, but I never before saw its colour on the purple side of red. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, May 24

Keen Sight of Fish

THE following extract from the remark book of Captain Robert A. Parr, of H.M.S. *Lyra*, may be of interest to your readers, bearing, as it does, such remarkable and trustworthy evidence of the keen sight of fish:—

"December 17th, 1867.—At noon, in lat. 0° 33′ S., long. 46° 13′ E., caught an Albacore, with 28 pistol bullets in its stomach. The ship's company had been exercised at pistol practice during the forenoon." G. F. M'DOUGALL

Hydrographic Dept., Admiralty, May 24

THE MULBERRY TREE

AN effort is being made to introduce once more into England the cultivation of the mulberry tree, and as the leaves of either the white or black variety (but especially those of the former) afford food for the silkworm, and both kinds will flourish in a tolerably mild and moist climate, there seems to be no reason why we should be altogether dependent upon foreign sources for a supply of raw material for the looms of Coventry and Macclesfield. Certainly the present is a favourable opportunity for making the experiment, as the price of silk has been largely enhanced by disease amongst the worms in the south of Europe, and by the destruction of the mulberry trees in China during the rebellion. At Yately, in Hampshire, Captain Mason has for the last three or four years been successfully engaged in rearing silkworms, and he calculates that if his mulberry plantations had been made upon a sufficiently extensive scale, a profit of 10*l.* an acre might have been easily realised. King James I. preceded him in this speculation, and imported ship-loads of mulberry trees from France with the view of encouraging the production of silk in England. In 1629 Walter Lord Aston was appointed "to the custody of the garden, mulberry trees, and silkworms near St. James's, in the county of Middlesex." But the scheme, like many others framed by the same monarch, proved abortive, and within a few years the mulberry garden became, in the words of Evelyn, "the only place of refreshment about the town for persons of the best quality to be exceedingly cheated at." Pursuing its history a little further we find the gardens converted into the site of Buckingham House, and in our own time Dr. King's allusion, written a century and a half ago, is a good deal more true than when he penned it:—

> The fate of things lies always in the dark;
> What cavalier would know St. James's Park?
> A princely palace on that space does rise,
> Where Sedley's noble muse found mulberries.

Within our own memory a similar experiment was tried in the neighbourhood of Slough, but it failed, not from any deficiency in the supply of food, but from the difficulty and expense incurred in tending the worms and carding the silk. Mechanical processes have now, in a great measure, removed these drawbacks, and the whole process of cultivation is one which would afford suitable employment for women and children.

The vicissitudes of fortune experienced by the mulberry tree in England belong to a curious chapter in the yet unwritten history of Botany. In common with the vine and several other trees, the mulberry has been alternately fostered and neglected: but in spite of royal favour and many intrinsic merits (for its fruit is wholesome and its timber valuable), it has now become a rare tree in Britain. The specimens at Sion House enjoy the reputation of being the first planted in England; but the probability is that the mulberry was introduced by the Romans, for the Saxon name for the tree "mor-beam," is little more than an echo of the Latin *morus*, which again can be traced to a still more Eastern source. The Sion House trees were, perhaps, some of those imported by James I., but their interest is far inferior to that which attaches to the celebrated tree planted at Stratford by Shakespeare's own hand, and ruthlessly destroyed by a Goth of modern times. C. J. ROBINSON

NEW TREES AND SHRUBS FOR ENGLISH PLANTATIONS *

WITHIN the last twenty years a complete revolution has taken place in the character of our out-of-door planting of ornamental trees and shrubs; trees which twenty years ago were rarities that a lover of arboriculture would go miles to see, are now to be met with in every gentleman's shrubbery or lawn with any pretensions to artistic arrangement. A really good hand-book was greatly wanted, to enable a planter to choose the species best suited to the climate, and best adapted to the special circumstances of his own particular estate. Such a hand-book Mr. Mongredien's "Planter's Guide" proposes to furnish, and to a great extent successfully. The plan of the book is admirable. We first have a list of 621 species of trees and shrubs, "selected from the large multitude which from time to time have been introduced from all parts of the world, and of which the vast majority are not worth cultivation for ornamental purposes." A brief description accompanies each name, with instructions as to the best aspect or position, and other needful particulars. These 621 species are then looked at from different points of view, and in the second part are classified accordingly: first, as to their height, then as to their foliage, next as to their flowers, and finally as to their fruit. Furthermore, we have selected lists of species remarkable for singularity of aspect, for rapidity of growth, suitable for hedges, thriving under the drip of trees or in the smoke of cities, adapted for different soils, &c. On looking closer into the manner in which this programme is carried out, we certainly find defects, as might be expected in a work which covers so much ground; but the defects are such as the author is sure to have brought under his notice, and which may easily be remedied in a second edition. Thus, although the list seems an extensive one, we miss many species, either old favourites or newly introduced, which ought to have had a place in it for their beauty or their useful properties: such as, among flowering shrubs, the *Berberis aquifolium*, a desideratum in every shrubbery, from its early flowering and the beautiful gloss of its evergreen leaves; *B. vulgaris*, the scarlet fruit of which is one of the most beautiful ornaments for the table; and the butcher's broom, *Ruscus aculeatus*, very easy of cultivation, and striking from the weirdness of its appearance, and the very peculiar growth of its flowers: and among climbing-plants, the common hop, used in some of the London parks in a very graceful manner to cover the stems of the poplar-trees. The list of plants thriving in the smoke of cities might also have been more than doubled by any of the author's friends who happen to have a London suburban garden. The illustrations interspersed here and there are very pretty; the frontispiece, however, a magnificent specimen of *Araucaria imbricata*, is unfortunate. If really taken from that tree, and not from another species of *Araucaria* not mentioned in Mr. Mongredien's list, it is very badly drawn.

ABIES PINSAPO BIOTA PENDULA

The introduction from China, about thirty years since, by Mr. Fortune, of a number of perfectly hardy evergreen conifers, previously unknown in this country, set the fashion among gardeners and planters strongly in that direction; and the proportion of this class, recommended in the "Planter's Guide," is very large. Out of the 621

* "Trees and Shrubs for English Plantations; a selection and description of the most ornamental trees and shrubs, native and foreign, which will flourish in the open air in our climate." By Augustus Mongredien. With Illustrations. (London: Murray, 1870.)

species, 254 are evergreens, 85 of them belonging to the coniferous tribe. As the author remarks, however, there are both advantages and disadvantages connected with the choice of evergreens for ornamental planting; while the persistent leaves of evergreens are generally of a dark and sombre hue, the young leaves put forth by deciduous trees in the spring are of a much brighter livelier tint, and during the summer months add much more to the freshness and beauty of the landscape. It seems probable that the great rage for new conifers is now somewhat going by, and that more attention will in future be paid to shrubs remarkable for the beauty of their flowers or fruit. A great acquisition has been the recent introduction of male plants of the *Aucuba japonica*, or common "variegated laurel," which thrives in every London garden or area. Till recently female plants only had been known in this country, which consequently never bore fruit. The fertilising of these by pollen, or the planting of a male plant, will ensure their being covered in the summer and autumn with a quantity of ornamental red berries.

There is much yet to be learnt with regard to the laws of acclimatisation and naturalisation. It appears by no means always to follow that we must look for trees and herbaceous plants suitable for introduction into our own country to those regions of the earth, the climate and soil of which most closely resemble our own. On looking over Mr. Mongredien's list, the countries which seem to have furnished the greatest number of perfectly hardy trees and shrubs are China and Japan, Northern India, Chili, California, and the more southern of the United States. Australia and New Zealand, on the other hand, have sent us very few species. A very large number of new kinds were introduced between 1840 and 1850; and we have therefore had no opportunity yet of knowing whether they will attain with us the size that some of them do in their native forests. An elm-tree eighty feet high is with us a fine tree; a very large number of the conifers are described in this work as attaining a height of from 100 to 140 feet, while the *Wellingtonia gigantea* of California, the monarch of trees, rears its head to the enormous altitude of 350 or 400 feet. Should our descendants witness their growth to their normal size, they will probably in many cases regret the want of forethought in their ancestors who planted them so near their houses; and at all events our parks and pleasure-grounds will present a very different appearance to what they do now. There is little doubt that a considerable number of trees and shrubs which are reckoned by gardeners to be half-hardy will, with a little care, grow very well out of doors in the southern counties of England. Even the Camellia requires, according to our author, protection for the first year or two only, to become a permanent and magnificently ornamental denizen of our shrubberies.

As a specimen of the author's style we may quote his description of the elegant *Cupressus Lawsoniana*:—

"California, 1852. Tree 60—80 feet. Leaves in alternate opposite pairs, closely adpressed, of a glaucous green. Branchlets slender, flattened, thickly clothed with leaves, gracefully pendulous, the leading shoots (as in the cedars) drooping until the ensuing season's growth; cones of the size of a large pea, with a glaucous bloom while young. This is one of the most beautiful trees of a beautiful tribe. It is very hardy, a rapid grower, and should find a place in every collection. It is frequently so laden with its beautiful cones (which, however, have more the appearance of berries) that the fruitful branchlets are quite borne down by their weight, like the boughs of a prolific apple-tree. Nothing can be more graceful or attractive."

GLEDITSCHIA TRIACANTHOS

Mr. Mongredien's book should be in the hands of every one interested in the planting of trees—and who is not who has the money to spend and the space to spare? The man who introduces on an extensive scale a new ornamental tree adapted to our climate performs a service to mankind, not only to his contemporaries, but to his descendants for many generations.

NOTES

HERE is some welcome news from the *London Gazette*—"The Queen has been pleased to appoint the most Noble William, Duke of Devonshire, K.G.; the Most Honourable Henry Charles Keith, Marquis of Lansdowne; Sir John Lubbock, Sir James Phillips Kay-Shuttleworth, Bernard Samuelson, Esq., William Sharpey, Esq., M.D., Thomas Henry Huxley, Esq., Professor of Natural History in the Royal School of Mines; William Allen Miller, Esq., M.D., Professor of Chemistry in King's College, London; and George Gabriel Stokes, Esq., M.A., Lucasian Professor of Mathematics in the University of Cambridge, to be Her Majesty's Commissioners to make inquiry with regard to Scientific Instruction and the Advancement of Science, and to inquire what aid thereto is derived from grants voted by Parliament, or from endowments belonging to the several Universities in Great Britain and Ireland, and the Colleges thereof, and whether such aid could be rendered in a manner more effectual for the purpose."

WE believe that the Government will propose to Parliament that the New Natural History Museum shall be built on the site occupied by the Exhibition of 1862, south of the Royal Horticultural Gardens. The ground was purchased some time ago for the sum of 120,000*l*.

THE annual visitation of the Royal Observatory, by the Board of Visitors is fixed for the 4th of June, at 3 p.m. The visitors, according to custom, will dine afterwards at the Ship.

MR. ERASMUS WILSON, who some time ago presented to the Council of the Royal College of Surgeons, of which institution he is a Fellow, the handsome sum of 5,000*l*., with which to endow a Professorship of Dermatology, has now devoted a further sum to the liquidation of the debt incurred by the College in fitting up the costly cases in the museum for the large and valuable collection of dermatological preparations since presented by him.

WE are requested to state that, to provide space at the South Kensington Museum for the examination and exhibition of the National Competition Drawings of the Schools of Art in the United Kingdom, the Gallery of Raphael's Cartoons will be used, and must be closed for a short time.

THE Council of the Royal Society have decided to recommend J. A. Ångström, of Upsala, and J. A. F. Plateau, of Ghent, to fill the two vacancies in the list of Foreign Members of the Society.

THE Commission of the Imperial Observatory of France for 1870 consists of the following members :—Members of the Council : President, M. Delaunay; Vice-president, Rear-Admiral de Penhoat; M. Balard, of the Academy of Sciences; M. Puiseux, of the Bureau of Longitudes ; M. Yvon Villarceau, M. Marié-Davy, M. Loevy, M. Wolff. Members of the Committee of Examination : President, Vice-Admiral Touchard, Rear-Admiral Baron Didelot, M. Faye, and M. Serret, members of the Institute; M. Briot, professor at the Faculty of Sciences, and M. Delaunay, director of the Imperial Observatory.

AS mentioned in our last number, the French Minister of the Fine Arts is in future to bear the title of Minister of Letters, Sciences, and the Fine Arts. The following duties and institutions are separated from the Ministry of Instruction to be attached to the new ministry :—The Imperial Institute of France ; the Imperial Academy of Medicine ; the Museum and Library of Algiers, and instruction in living Oriental languages ; the Imperial School of Letters Patent ; the Imperial Library and curriculum of Archæology which are attached to it ; the Mazarin library, and those of the Arsenal and St. Geneviève ; the general care of the libraries, and editing the catalogues of the libraries of the departments ; the learned societies of Paris and of the departments ; the *Revue des Sociétés savantes*, and library of the committee of historical works, and of the learned societies ; the *Journal des Savants* ; subscriptions to scientific and literary works, and distribution of these works among the public libraries ; the consulting committee of subscriptions and committee of historical works ; encouragement and assistance to scientific and literary men ; subsidies and encouragements for voyages and scientific and literary missions ; publication and distribution of the unpublished documents concerning the history of France and topographical map of Gaul ; the legal dêpot ; reception and distribution of works proceeding from the legal dêpot. And all this time *we* have not even a Minister of Public Instruction !

THE annual Rede lecture was delivered on the 18th inst. in the Senate House, Cambridge, by Prof. W. A. Miller, of King's College, London, to a numerous audience, the subject being, "Aniline, and the various Products of Coal-tar." The lecture, which was eloquently delivered, and was illustrated by many beautiful and successful experiments, was listened to with great attention ; and at the conclusion a vote of thanks, proposed by the Vice-Chancellor and seconded by Professor Sedgwick, was carried enthusiastically. The honorary degree of LL.D. was afterwards conferred on Prof. Miller and on Mr. Huggins, the Rede lecturer of last year.

THE council of the Senate of the University of Cambridge have referred the report of the Physical Science Syndicate back to that body, with a request that they would reconsider it, having regard to the late debate in the Arts Schools, the general tone of which was decidedly adverse to the scheme recommended by the Syndicate, and favourable to the general principle of the fund being raised by some system of taxation of the College revenues.

WE are extremely glad to learn that Trinity College, Cambridge, has instituted a Prælectorship of Pure Physiology, and that Dr. Michael Foster, who has for some years been Professor of Practical Physiology at University College, has been appointed the first occupant of the chair. This will, we trust, give great impulse to the study of Natural Science, especially of Biology, in Cambridge. Trinity College could scarcely have found a more earnest, able man, and a better teacher than Dr. Foster.

DR. CARPENTER will deliver a lecture "On the Physical and Biological conditions of the Deep Sea," in the Senate House of the University of Cambridge, to-morrow, at 2.30 P.M.

THE "Sars Fund" in this country now amounts to 343*l*. 12*s*. 10*d*., and we understand that it will soon be closed. Every zoologist and geologist has subscribed ; but there are many lovers of science and of Scandinavia to whom we may venture to make a last appeal on behalf of this truly deserving and interesting case. Some copies of the *carte de visite* of the late Professor Sars will soon be received by Mr. J. G. Jeffreys for those subscribers who may care to possess such a memorial.

THE Admiralty have acceded to the request of the Royal Society by again placing Her Majesty's surveying steam-vessel the *Porcupine* at their disposal for another deep-sea exploration, to commence in the latter part of June. Mr J. Gwyn Jeffreys will take charge of the first cruise, which is intended to be across the Bay of Biscay, along the coasts of Spain and Portugal, to Gibraltar. Dr. Carpenter will there succeed him in the beginning of August, and proceed into the Mediterranean, after endeavouring to trace the direction and nature of the currents at the Straits. Prof. Wyville Thomson will probably join Mr. Jeffreys. A photometric apparatus has been contrived by Mr. Siemens for the purpose of ascertaining the depth to which solar light penetrates the sea ; and other questions of considerable interest will be investigated in this expedition. But we regret to find that the time is so limited for such an important object.

AT the anniversary meeting of the Royal Geographical Society held on Monday last, the Founder's Medal was awarded to Mr. George W. Hayward, the Society's envoy to Central Asia, for the map of his journey across the Kuen Lun into Eastern Turkistan, and for the perseverance with which he is endeavouring to carry out his object of reaching the Pamir Steppe. The Patron's, or Victoria Medal, to Lieutenant Francis Garnier, of the French navy, second in command of the French Exploring Expedition from Cambodia to the Yang-tsze-Kiang, for the part he took in the extensive surveys executed by the commission, for his journey to Tali-fu, and for the ability with which, after the death of his chief, Captain de la Grée, he brought the expedition in safety to Hankow. The medals presented by the society to the chief public schools were awarded to G. G. Butler, Liverpool College; M. Stuart, Rossall School; G. W. Gent, Rossall School; and J. H. Collins, Liverpool College. Sir Roderick Murchison, in the course of his opening address, said that he grieved at being unable to offer some encouraging sentences on the prospect of speedily welcoming Dr. Livingstone home; at the same time (he proceeded) there is no cause for despondency as to his life and safety. He had been for some time at Ujiji, on the Lake Tanganyika, whence he wrote home on the 30th May last, though unable to make any movement for want of carriers and supplies. These were, indeed, forwarded to him by Dr. Kirk from Zanzibar, when an outbreak of cholera stopped and paralysed the relieving party. Recent intelligence, however, has reached the Foreign Office to the effect that the pestilence had subsided to so great an extent that we may presume the communication between the coast and Ujiji has before now been reopened. The work which still lies before Livingstone has been often adverted to, and it is hoped that he will live to advance to the north end of the Tanganyika, and there ascertain if its waters flow into the Albert Nyanza of Baker. If the junction should be proved, we may indulge the thought that, informed as Livingstone must now be of the actual carrying out of the great project of Sir Samuel Baker, he may endeavour to meet his great contemporary. The progress of the great Egyptian expedition of Baker having been delayed in its outset, we know that it only left Khartoum to ascend the White Nile in February. After reaching Gondokoro, as was expected to be the case in the first days of March, some time must necessarily elapse in establishing a factory above the upper rapids, and beyond the tributary Asua, where the steam-vessels are to be put together before they are launched on the Nile water, on which they are to pass to the great Lake Albert Nyanza. As soon, however, as a steamer is on that lake, we may be assured that Baker, with his well-known energy and promptitude, will lose not a moment in the endeavour to reach its southern end, in the expectation of there giving hand and help to Livingstone.

THE paragraph inserted among our "Notes" of April respecting Mr. Wilson Saunders's collection of "mimetic" plants at the recent Linnean *soirée* having been copied by our able contemporary the *Gardener's Chronicle*, a correspondent in that paper asks for a complete list of the mimetic pairs. In giving us the list, Mr. Saunders states that the plants were none of them grown for the purpose, but simply selected from his greenhouse on the spur of the moment for the purposes of the *soirée*.

Olea europæa	Oleaceæ
Swammerdamia Antennaria	Compositæ
Kleinia ficoides	Compositæ

AN admirable article appears in the *British Medical Journal* for May 21st, on Government Honours to Medical Science. Starting with Faraday's reply, when consulted by the Government of the day as to the propriety of a more liberal distribution of titles and other honours amongst men of science, that "Government should, *for its own sake*, honour the men who do honour and service to the country," the writer shows how this principle might be carried out by the appointment of Medical Sanitary Inspectors for the whole country, instead of merely for large towns; of State Inspectors of Civil Hospitals; and other similar arrangements.

WE quote from the *Moniteur Scientifique*:—"M. R. Wolf, of Zürich, has just published the *résumé* of his observations on the solar spots made since 1864. The minimum occurs in 1867, and agrees with the period of $11\frac{1}{9}$ years, found by Sabine and himself. Designating the relative frequency of the spots by r, M. Wolf expresses the variation of the magnetic declination at Christiania by the formula $v = 0'\cdot0413r + 4'\cdot921$, which does not, however, completely agree with observation."

WE quote the following from the *Pall Mall Gazette* for the benefit of our Darwinian readers:—"Two new birds have arrived at the Zoological Gardens the alleged habits of which afford a curious theme for speculation, and serve to supply an illustration to poets and philosophers. The male has a strong, short, curved beak; the female, a much longer bill. The naturalists tell us that the male breaks open the bark of the tree, within which lies hid the grub on which they feed; and the female pulls out the worm and presents her mate with half the meal. Here is a delightful instance of the essential incompleteness and mutual helpfulness of the sexes, the two forming one, as we are told they should, in perfect conjugal union. We hope that observation may confirm the tale; but animals at the Zoological Gardens are painfully apt to disappoint the expectations which we have been led to form of them. There is the aye-aye, for instance. Every one has heard of its marvellously long nail, and its singular adaptation to the necessities of the creature's existence. Professor Owen has founded an exquisite argument on the use of the long nail in extracting the creature's food from the deep crevices in which it is supposed to find it. It is an admirable instance of design. But although all sorts of ingenious devices have been adopted to induce the aye-aye to use its nail for these purposes, it seems to have a rooted objection to do so, and has never been known to do anything else than scratch its nose with it, which nobody can suppose to be a final cause."

WE have received from the Colonial Government of Victoria a copy of the Reports of the Mining Surveyors and Registrars for the quarter ending 31st December 1869, containing the Gold Mining Statistics for the quarter, the estimated yield of gold and quantity of gold exported; the summary of yield of gold from quartz, quartz tailings, &c., crushed; and the number and distribution of miners on the gold fields of the Colony on the 31st of December.

THE Botanical Garden at Rotterdam is about to be suppressed by the communal administration. M. Rauwenhoff, the director, and M. Witte, the head gardener, have given this information to their European *confrères*.

A JOURNAL of Horticulture has been started in Portugal under the title of *Journal de Horticultura Pratica de Portugal*, by M. José Marques Loureiro. M. Welwitsch has shown how wide a field for further exploration by botanists still remains in the Portuguese settlements in Africa.

A NINTH supplement to the Annals of the Munich Observatory is published, containing the particulars of 4793 telescopic stars between -3° and -9° declination, together with the observations of Lalande, Bessel, Rümker, and Schjellerup.

THE ABRADING AND TRANSPORTING POWER OF WATER

III.—PRACTICAL CONCLUSIONS

HAVING on two former occasions, when treating of the abrading and transporting power of water (which is supposed to increase as the velocity increases, but to decrease as the depth increases), dwelt on the mechanical property of water, and shown how it rolls rather than slides: the following conclusions may be arrived at:—

I. That all particles of water have an affinity to each other as well as to other bodies, and that force is required to separate them;

II. That friction sets these particles rotating in all directions in larger or smaller circles, and that the friction or force increases in some proportion to the area of surface exposed;

III. That this rolling motion becomes rarer the larger the diameter of the circles may be, that is, the resistance decreases as the depth and breadth of a stream increase, or in other words, the velocity increases proportionally to the "hydraulic mean depth;"

IV. Lastly, that any increase to the rapidity of this rotatory motion, must increase the abrading and transporting power of water, by enabling it to remove from the channel of a stream grains of solid matter, and hold them in suspension.

The following deductions are arrived at:—

1. That a smooth surface offers the smallest area for the water to attach itself to, and fewer irregularities; consequently the rotatory motion given to the water is reduced to a minimum, that is, the power expended is least, or the friction among the particles of water flowing through a smooth uniform channel is less than when it flows through an irregular and rough one.

2. That in the lines of a ship not only should there be no sudden changes in direction, but the surfaces should be as smooth as possible.

3. That the area of this surface should be as small as possible; hence convex lines are preferable to concave ones, as with the same area they afford greater buoyancy, while there would be less friction for the water to roll along a convex surface than a concave one.

4. That additional length given to a ship, leaving out all other questions, must retard a ship passing through the water, by increasing the area exposed to friction; consequently there is probably some limit owing to this increased resistance, where the length midships should not exceed certain proportions of the midship section.

5. That a ship passing over shallow water must be retarded, as the diameter of the vertical circles revolving under her bottom must be less than the diameter of the circles where the water is deep; hence the smaller circles will be set in quicker rotation, and therefore loss of power ensues.

6. That the same will be the effect from the same cause where the channel is narrow and contracted.

These deductions apply to cases where the abrasion may be considered "nil," such as the discharge of water through pipes, and the sailing of ships; and the practical conclusion is, that for pipes with glazed surfaces, and ships having coppered bottoms, the water passes with the least friction.* In the case of ships, *speed* is not the only question to be considered, so the subject becomes very complicated, and though believing in the general soundness of the above deductions, the solution of these problems may be left to the naval architect to consider.

Viewing the subject on the large scale, very important conclusions are arrived at from these facts—namely, that the depth of a river depends on the nature of the materials it has got to transport; thus those which have to carry down coarse sand should be broad and shallow, while those which have to convey fine mud would naturally be narrow and deep. And as this depends on the geological nature of the catchment basin of the river, are we not naturally led to the conclusion that where we find rivers navigable, the rocks of the catchment basin which predominate are of an aqueous formation, while those rivers which are difficult of approach from the sea must drain a country where crystalline rocks predominate? Judging, therefore, on this hypothesis, are we not right in conjecturing that the rocks of Central India, and also of that vast, but hitherto almost unexplored, country, Central Africa, must be generally of a crystalline nature?

This interesting question, however, like that of the best form of ships, had better be left for the consideration of the professional inquirer, whose investigations lead him to study that branch of geology which treats of the denudation of rocks now going on on the earth's crust, and the deposits now being formed. I pass on to those questions which affect the hydraulic engineer, and they are so numerous that it would be difficult even to enumerate and classify them, while their importance is so great that it can hardly be over-estimated. On this occasion only one or two of the more prominent subjects will be glanced at, more for the purpose of leading to future investigation, than to lay down rules for guidance, which at this present stage it would be premature to attempt.

From the foregoing remarks, suggestions, and deductions, it may be supposed that there are certain laws of nature which adapt each case to its own particular circumstances. Take, for example, the course of a river. It has been before said that streams which have to transport coarse, solid matter, such as sand, are usually broad and shallow, while those which convey chiefly fine mud are deep and narrow. The reason why those streams which convey a large proportion of sand should be broad and shallow, is that the water has thus sufficient power to hold the solid matter in suspension; and to still further aid them in this, it will be often observed that Nature generally gives such rivers comparatively speaking straight channels, in comparison to those which convey fine mud. The object in this case would appear to be that Nature in the former instance takes the shortest route, so as to obtain as great a fall as possible in the bed of the stream; while with the deep muddy stream, to prevent the water rushing off too fast, and so to keep up the surface of the stream to a level with the banks, or in floods often above them, Nature takes her tortuous courses, and is thus enabled year after year to deposit those fine grains of mud which add so much to the fertility of the soil.

So evidently is this the case, that in Egypt the irrigation canals are all carried in a zigzag direction, so as to check the velocity, and prevent the coarser particles of solid matter from being transported, while at the same time the surface of the water is kept at a sufficient elevation, so as to admit of easy irrigation. Thus, probably, Joseph, or whoever started irrigation in the land of the Pharaohs, took a leaf out of Nature's book; and it is by the study of this volume that the engineer of the present day will be most certain to arrive at satisfactory results.

That rivers have certain general principles by which they are governed, as to breadth, depth, slope, velocity, and load of solid matter held in suspension, it appears reasonable to suppose; and any change introduced in any

* On reading over the above conclusions to an experienced ship-builder here in London, he said that one of the reasons why Aberdeen clippers sailed so fast, was owing to the smoothness of the ships' bottoms, which were first planed before the copper was put on. He also remarked that where the copper is very smoothly put on, the first place where the sheet wears through is just behind where the sheets overlap, showing that even an irregularity of $\frac{1}{16}$ of an inch causes an extra action, not as might be supposed at the point of greatest obstruction, but just beyond it, proving that there must be this whirling motion which causes this abrasion. This gentleman also observed that experience showed that the speed of a ship chiefly depends on the fineness of the lines of the after rim of a ship, and that "ingoing" or concave lines should be avoided if possible.

one of these proportions must cause a corresponding change in one or all of the above conditions.

Thus, let there be a stream which in flood contains 5 per cent. by weight of solid matter, and let it be 8 ft. deep, discharging 50,000 cubic feet a second, with a mean velocity of $7\frac{1}{2}$ ft. a second—the breadth of this stream would be $\frac{50,000}{8 \times 7\cdot5} = 833\frac{1}{3}$. To add one-fourth to the discharge of this stream of pure water would increase the discharge from 50,000 to 62,500 cubic feet a second, and the proportion of solid matter, instead of being 5 per cent., would be only 4 per cent. But, by the example before given, a depth approaching 9 ft. instead of 8 ft. would be the natural depth, so the bed would be lowered 1 ft., and the breadth would only be increased $\frac{12,500}{2 \times 9 \times 7\frac{1}{2}} = 92$ ft., instead of having to give an increase of one-fourth more, or $\frac{833}{4} = 208$ ft., and still keep matters much as they are found in nature.

So in bridging such a stream the whole additional length of viaduct would be only 92 ft., or 116 ft. would be saved by simply sinking the foundations 1 ft. more. But as water rolls rather than slides, and never flows in straight lines, the shape of the section of a stream can be changed at pleasure; so the depth may be increased without much danger by decreasing the breadth. Taking, then, the same stream which it was proposed to make $833 + 92 = 925$ ft. broad by 9 ft. deep, suppose the mean depth be made 15 ft., this increase of depth would decrease the transporting power, while at the same time the velocity would also be increased; and suppose it to be now 10 ft. a second, instead of $7\frac{1}{2}$ ft., and with a depth of 15 ft. with such a velocity only 4 per cent. of solid matter could be held in suspension, and the waterway would be $\frac{62,500}{15 \times 10} = 416\frac{2}{3}$ ft. broad instead of 925 ft., or less than one-half. That is, by adding 8 ft. to the general depth of a stream where the river discharges 50,000 cubic feet a second in the main channel, and 12,500 cubic feet a second of inundation water, which is comparatively free of silt, the whole volume or 62,500 cubic feet could be passed through a bridge only half the breadth of the original stream, which was 833 ft. broad. So the whole question reduces itself now into one of cost.

The question is whether it be cheaper to sink the foundations an extra 8 or 10 ft., or to double the length of viaduct. By the use of the sand-pump foundations can now be sunk through sand at a very moderate cost; so it is believed that the extra sinking would not involve anything like the cost of the shallower foundations for the bridge built on the extended plan; thus the whole cost of the superstructure and extra girders could be saved—that is speaking approximately. In such a case the bridge built on this deep foundation principle could be built at nearly half the cost of the old plan; but to guard against accidents, and scooping out to excessive depths, it would appear that at least one-third may be saved by building bridges on this principle; while the river, by having a deep channel under the bridge, could be kept in better control than by the present extended method, as it would not have such a tendency to desert its course, but would always keep to the deep channel.

Several other examples may be brought forward to illustrate the practical advantages that a better knowledge of the action of flowing water would be sure to confer on science and hydraulic engineering; but it is hoped that the foregoing will assist in bringing the importance of the subject more prominently forward. When once the subject is properly discussed I am convinced its importance will be manifested.

SOCIETIES AND ACADEMIES

LONDON

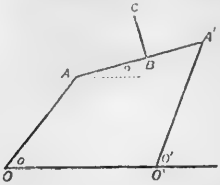
Royal Society, May 19.—"Experiments on the Effects of Alcohol (*Ethyl Alcohol*) on the Human Body." By E. A. Parkes, M.D., F.R.S., Professor of Hygiene in the Army Medical School, and Count Cyprian Wollowicz, M.D., assistant-surgeon, Army Medical Staff.

"On Deep-sea Thermometers." By Staff-Commander John E. Davis, R.N. Communicated by Captain Richards, R.N., Hydrographer of the Admiralty. The results of thermometric observations at great depths in the ocean not being of a satisfactory nature, the attention of the hydrographer of the navy was directed to the defects in the construction of the Six's self-registering thermometers then in use, and also to the want of knowledge of the effects of compression on the bulb; and as it was known that a delicate thermometer was affected *in vacuo*, it was natural to suppose that an opposite effect would be had by placing them under pressure, and particularly such as they would be subjected to at great depths. Several thermometers, of a superior construction, were made by different makers, and permission was granted to make experiments by pressure in a hydraulic press; but much delay was caused by not being able to obtain a press suitable to the requirements, until Mr. Casella, the optician, had a testing-apparatus constructed at his own expense, and the experiments were commenced. Previous to the experiments being made, Dr. W. A. Miller, V.P.R.S., proposed, or rather revived, a mode of protecting the bulb from compression by encasing the full bulb in glass, the space between the case and the bulb being nearly filled with alcohol.* A wrought-iron bottle had been made to contain a thermometer, for the purpose of comparison with those subjected to compression; but it failed, and finally burst under great compression; it proved, however, of but little consequence, as those designed by Dr. Miller showed so little difference under pressure that they were at once accepted as standards. Two series of experiments were then most carefully made, at pressures equal to depths of 250, 500, &c., to 2,500 fathoms, the results of which satisfactorily proved that the strongest made unprotected thermometers were liable to considerable error, and therefore that all previous observations made with such instruments were incorrect. Experiments were also made in the testing-apparatus with Sir Wm. Thomson's enclosed thermometers, to ascertain the calorific effect produced by the sudden compression of water, in order to find what error, if any, was due to compression in the Miller pattern: an error was proved to exist, but small, amounting to no more than $1^\circ\cdot4$ under a pressure of 3 tons to the square inch. The dredging cruise of the *Porcupine* afforded an opportunity of comparing the results of the experiments made in the hydraulic testing apparatus, with actual observation in the ocean, and a most careful series of observations were obtained by Staff-Commander E. K. Calver at depths corresponding to the pressure applied in the testing apparatus; the result was that, although there was a difference in the curves drawn from the two modes of observation, still the general effect was the same, and the *means* of the two were identical. From these experiments and observations a scale has been made by which observations made by thermometers of similar construction to those with unprotected bulbs can be corrected and utilised, while it is proposed that by means of observations made with the Miller pattern in the positions and at the same depths at which observations have been made with instruments not now procurable for actual experiment, to form a scale for correcting all observations made with that particular type. In conclusion, it is suggested that to avoid error from the unsatisfactory working of the steel indices, which, from mechanical difficulties in their construction, cannot always be depended on, two instruments should be sent down for every observation; and although their occasional disagreement of record may raise a doubt, a little experience will enable the observer to detect the faulty indicator, while their agreement will create confidence.

London Mathematical Society, May 12.—Prof. Cayley, president, in the chair. The Hon. Sir J. Cockle, Chief Justice of Queensland, was proposed for election.—The President (Mr.

* *Vide* Proceedings of the Royal Society, vol. xvii. No. 113, June 17, 1869.

Spottiswoode, V.P., having taken the chair) gave an account of his paper "On the Mechanical Description of a nodal bicircular Quartic." Take a quadrilateral OAA′O′, in which the adjacent



sides OA, AA′ are equal to each other, and the other two adjacent sides OO′, O′A′ are also equal to each other. O, O′ are fixed points, and we have thus a link, AA′, the extremities of which are connected with the radii OA, O′A′, respectively, and consequently describe circles about the centres O, O′ respectively, the radius OA of the one circle being equal to the length AA′ of the link, and the radius O′A′ of the other circle being equal to the distance OO′ of the centres. The theorem is that any point C rigidly connected with the link AA′ describes a nodal bicircular Quartic; that is, a quartic curve with three nodes, two of the nodes being the circular points at infinity. Any such curve is the inverse of a conic, and it is also the antipode of a conic. For the analytical investigation, the origin is taken at O, the axis of x in the direction OO′, and the axis of y at right angles thereto, upwards from O. The inclinations of OA, AA′, O′A′ to the axis Ox are taken to be θ, ϕ, θ' respectively. Also write OA = AA′ = a, AB = b,

BC = c, OO′ = O′A′ = a^1, and make $m = \dfrac{a^1 - a}{a^1 + a}$ then

we have for the locus of C—

$$x = a \cos\theta + b \cos\phi - c \sin\phi$$
$$y = a \sin\theta + b \sin\phi + c \cos\phi;$$

since $\theta^1 = \theta + \phi$. Also we have $\tan\frac{\theta}{2} \tan\frac{\phi}{2} = m$;

whence writing $\tan\frac{\theta}{2} = u$, we have $\tan\frac{\phi}{2} = \frac{m}{u}$ and the equation to the locus may be written—

$$x = -a\frac{u^2 - 1}{u^2 + 1} + b\frac{u^2 - m^2}{u^2 + m^2} - c\frac{2mu}{u^2 + m^2}$$

$$y = a\frac{2u}{u^2 + 1} + b\frac{2mu}{u^2 + m^2} + c\frac{u^2 - m^2}{u^2 + m^2};$$

which equations show that the locus is a bicircular quartic. The author then proceeds to show the existence of a third node, to express the locus as the inverse of a conic, and to exhibit it as the antipode of a conic. In the discussion on the paper Mr. Roberts gave some additional results bearing on the subject; and Mr. Spottiswoode stated that he recognised many of the curves (exhibited by Messrs. Cayley and Roberts) as having come under his notice in the course of experiments he had recently made with elastic strings.

Mr. Roberts then read his paper "On the Ovals of Des Cartes." It will suffice in this notice to give the heads under which the author treated the subject. On the polar equation and its interpretation; on the description of the curves by the transformation of a circle; on certain systems of the curves; on the normals; properties deducible from the general interpretation of the polar equation. Under the last head Mr. Roberts stated some interesting results: the sum of the areas of the Ovals—that is to say, in an obvious sense, the area of the Cartesian is equal to twice the area of the circle whose centre is at the triple focus, and which passes through the points of contact of the double tangent; the lengths of the ovals of a Cartesian are expressed by Zyzygetic relations between two elliptic quadrants; the difference of the lengths of the loops of a nodal Limaçon is four times the distance between the vertices.—Dr. Henrici exhibited a plaster cast of the surface, $xyz - \left(\frac{3}{7}\right)^3 \left(x + y + z - 1\right)^3 = 0$.

Royal Astronomical Society, May 13.—W. Lassell, F.R.S., President of the Society, in the chair. Thirty-one presents were announced, and the thanks of the society were voted to the respective donors. Prof. Selwyn read a communication from Sir John Herschel, referring to a chart in which the sun's spots observed by Mr. Carrington during his long study of the sun have been referred to their proper solar longitude and latitude. Sir John Herschel's object in preparing this chart was to determine what signs there are that any particular portions of the sun within the sun-spot latitude are more liable than others to be the scene of spot-formation. He found very few signs of any such arrangement. Mr. Proctor remarked that Sir John Herschel's communication seemed to dispose effectually of Prof. Kirkwood's recently propounded theory in explanation of the periodicity of sun-spots.—Papers on the occultation of Saturn, as observed by Messrs. Talmage, Joynson, and Captain Noble, were then read. Captain Noble remarked on the singularly clear definition of Saturn, "right up to the moon's limb," as being strikingly opposed to the theory brought forward by Mr. Watson at the last meeting of the society.—A paper by Mr. Penrose, on the Sun-spots recently seen, led to some controversy about the real nature of the spots. Mr. Howlett dwelt on the exaggerated character of the saucer-shaped depressions usually shown in text-books of astronomy. Mr. De La Rue mentioned the preponderance of evidence in favour of the spots being depressions. The Astronomer Royal also spoke in favour of this view. Mr. Lockyer dwelt on the evidence bearing on the subject derived from his method of detailed spectroscopic examination, and mentioned the interesting circumstance that so far as his spectroscopic observations had hitherto gone, it seemed almost as though the depressions were shallower now the spot period was nearly at its maximum than they were a year and a half ago. The Astronomer Royal expressed his admiration of the persistence and patience with which Mr. Lockyer had continued his solar observations, and stated his belief that in the course of the next two or three years we should gain much more new knowledge from this application of spectroscopic analysis to the sun.—At the President's request, Mr. Airy then referred to the expedition to be made to observe the eclipse of December next. He stated that the names of about sixty volunteers had been received. According to present arrangements, as many as twenty-six would be wanted at each station for general, spectroscopic, polariscopic, and photographic work. He expressed his anxiety that the observers who were to take part in the observations on the polarisation of the corona's light should understand their work, and clearly recognise—1st, what polarisation is; 2nd, what polarisation in a plane means; and, 3rd, when light *is* polarised in a plane how to recognise that plane. Mr. De La Rue spoke very favourably of the list of volunteers, saying that it included just those classes of observers which were really wanted. It was mentioned that the Poet Laureate had volunteered; and, in answer to a question by Prof. Grant, that good draughtsmen would accompany the expedition.—A paper by Mr. Lynn, on a star in Ursa Major, which has a very large proper motion, according to the researches of Argelander, was then read.—Mr. Proctor read a paper, "On the Resolvability of Star-groups regarded as a Test of Distance," dwelling on the evidence we have of variety of constitution as at least equally available to explain differences of resolvability as variety of distance can be. Mr. Stone said he thought Mr. Proctor exaggerated the theory of uniformity of stellar distribution; in reality, astronomers regarded the existence of very various degrees of real magnitude among stars as not only possible but probable, or even certain. Mr. Proctor said he was fully aware of that, and his views touched on quite a different matter. What he pointed to as wrong in accepted theories was that those theories failed to recognise the existence of definite aggregations of stars, in streams, clusters, groups, and so on, showing all degrees of richness of aggregation, &c.—Mr. Williams then described some antique telescopes of Campani's construction, amazingly long, with object-glasses varying apparently from about half an inch to an inch in diameter.

Zoological Society, May 12.—Prof. Newton, vice-president, in the chair. The secretary read some notes on the principal additions to the Society's menagerie during the month of April, and called particular attention to a Vulturine Guinea-fowl (*Numida vulturina*), presented by Dr. John Kirk, C.M.Z.S., being the first living specimen of this rare species received in England.—A communication was read from Dr. R. O. Cunningham, C.M.Z.S., on some peculiarities in the anatomy of three kingfishers, *Ceryle stellata*, *Dacelo gigas*, and *Alcedo ispida*.—A communication was read from Mr. George Gulliver, F.Z.S., on the taxonomic characters afforded by the muscular sheath of the œsophagus in sauropsida and other vertebrates.—Mr. R. B. Sharpe read a paper containing a full account of the swallows

(*Hirundinidæ*) of Africa, and pointed out their characters and geographical distribution. Particular attention was drawn to the affinities of the African *Hirundinidæ* with those of the New World, and also to the representation of various species by smaller races or sub-species throughout the Æthiopian region. Thirty-eight species of swallows were enumerated, of which number thirty were stated to be peculiar to the continent of Africa, and two to Madagascar and the adjacent islands. Two species only were common to India and Africa, and the remaining four were migratory throughout the Palæarctic and Æthiopian regions.—Dr. O. Finsch, C.M.Z.S., communicated the description of a new species of penguin in the collection of the Counts Turati, of Milan, which he proposed to call *Dasyrhamphus herculis*.—Messrs. P. L. Sclater and O. Salvin read descriptions of seven new species of birds collected by Dr. Habel during a recent expedition to the Galapagos Islands. These new species were mostly from Bindloes Island and Abingdon Island, which had not been visited by former explorers, and belonged principally to a peculiar group of *Fringillidæ*, containing *Geospiza* and its allied forms, which is characteristic of the Galapagoan Archipelago.—Mr. P. L. Sclater, F.R.S., read a paper on some new or little known species of South American birds, amongst which was a new woodpecker, proposed to be called *Melanerpes ulcher*, from New Granada.—Prof. Flower, F.R.S., communicated some additional notes on the specimen of the common fin whale (*Physalus antiquorum*) recently stranded in Langston Harbour.—Prof. Newton read a paper "on *Cricetus nigricans* as an European species," and exhibited a specimen of this mammal which had been lately killed in Bulgaria by Mr. T. E. Buckley, F.Z.S., and had been presented by him to the Cambridge Museum.

Leeds

Philosophical and Literary Society, May 3.—At the annual meeting, being the close of the fiftieth session of the Leeds Philosophical and Literary Society—Dr. Heaton, the retiring president, in the chair—it was announced that the following gentlemen had been elected as officers, council, and members for 1870-71:—President, John Deakin Heaton, M.D., F.R.C.P.; Vice-Presidents, C. Chadwick, M.D., F.R.C.P., Thomas Nunneley, F.R.C.S.; Treasurer, Henry Oxley; Honorary Secretaries, Thomas Wilson, M.A., Richard Reynolds, F.C.S.; Honorary Curator in Geology, J. G. Marshall, F.G.S.; Honorary Curators in Zoology, Edward Atkinson, F.L.S., T. C. Allbutt, M.A., M.D., F.L.S., F.S.A.; Honorary Curator in Ethnology and Works of Art, &c., Thomas Nunneley, F.R.C.S.; Honorary Librarian, John Deakin Heaton, M.D., F.R.C.P. The above officers, and the following gentlemen, compose the Council:—John Edwin Eddison, M.D., E. Filliter, M. Inst. C.E., F.G.S., T. M. Greenhow, M.D., Joshua Ingham Ikin, F.R.C.S., Rev. J. H. M'Cheane, M.A., John Manning; T. W. Stansfeld, Rev. H. Temple, William Sykes Ward, F.C.S., Rev. Canon Woodford, D.D., General Curator and Assistant Secretary, Henry Denny, A.L.S.

Paris

Academy of Sciences, May 16.—The following mathematical papers were read:—Researches on pencils of right lines and normals, containing a new exposition of the theory of the curvature of surfaces, by M. A. Mannheim, communicated by M. Bertrand; a note on a peculiar property of the cassinoid with 3 foci, $p^6 - 2\,mp^3 \cos 3\,\theta = \pm 1$, by M. Allegret; and a note on the solution of the problem consisting in finding three whole numbers, such that the square of the one shall equal the sum of the squares of the other two. M. Bertrand also presented a report on a memoir by M. Moutard on the theory of partial differential equations of the second order.—M. Lecoq de Boisbaudran presented some remarks on the spectra of nitrogen, in which, after noticing his observations on this subject, he concluded that the changes of the spectra of this, and probably of other bodies, depend upon variations of temperature rather than of pressure, a circumstance which ought to lead to great caution in the astronomical application of spectrum analysis.—M. Regnault presented a note on the maximum of density and the temperature of congelation of solutions of alcohol in water, by M. F. Rossetti. These temperatures decrease in proportion to the amount of alcohol in solution.—M. Leray communicated a theory of the elasticity of media deduced from the principle that equal currents crossing in all directions exist in the midst of ether when not influenced by surrounding bodies; and M. Delaurier presented a description of a battery for ringing telegraphic bells.—A communication from Father Secchi, containing the rectification of a numerical error in his last paper, was read, and in connection therewith M. Fizeau communicated some remarks on the displacement of the spectral rays by the movements of the luminous body or of the observer. A memoir on the theory of the tides, by M. Roumiantzoff, was read; also a note by M. Trémaux on some questions relating to the movements of the planets.—M. Guyon presented a note on a meteorological observation made by the washerwomen of the south coast of Spain. The observation was that with a southerly wind linen put out to dry always acquires a yellow colour; the author accounted for it by assuming that this coloration is due to impalpable dust conveyed from the African deserts.—M. A. Wurtz described a process for obtaining solid cresole, and some curious properties possessed by that body.—M. F. M. Raoult communicated a note on the composition of the gas of the burning spring of Saint Barthélemy (Isère) It consisted chiefly of marsh gas, 98·81 per cent. by volume, with small quantities of carbonic acid, nitrogen, and oxygen probably accidentally mixed with it.—M. Guyot presented a note on the examination of ammonia and nitric acid by means of rosolic acid and bromomercurate of potash.—M. Belgrand communicated a general account of the contents of his great work on the basin of Paris in prehistoric times, which has lately been published by the municipal administration of Paris.—M. Farez recommended the employment of silicate of potash for the purpose of giving solidity and cohesion to friable fossil bones.—M. Brongniart presented a report on a memoir by M. B. Renault, on some silicified plants of the neighbourhood of Autun.—A note was read from M. Marey, admitting that Dr. Pettigrew had the priority over him with regard to the figure of 8 described by the wing of an insect during flight; and M. A. Dumeril presented a note by M. S. Legouis on the pancreas of the osseous fishes and the nature of the vessels discovered by Weber. The author described three forms of pancreas occurring in osseous fishes, which he called the *disseminated*, *diffused*, and *massive* pancreas; the vessels discovered by Weber are the excretory ducts of the first two forms. The Plagiostomi have a pancreas resembling that of the higher animals.—A note from M. Didierjean was read, calling attention to the fact that milk is a preservative from the poisonous effects produced by lead upon the workmen who are engaged in the preparation of its compounds.—M. E. Decaisne presented a note on the use of the sewing machine and its influence on the health of workwomen. He considers that the ill effects of working with the sewing machine have been greatly exaggerated, and that the health of women working with the machine is quite as good as that of needlewomen.

Berlin

German Chemical Society, April 25.—H. Limpricht published a paper on oxyde of toluylene, to which he ascribes the formula $C\,H_2\,O\,C\,(C_6\,H_5)_2$.—M. Topsoë sent in a paper on preparing concentrated bromhydric acid, and a table on the boiling points of hydrobromic acids of different concentration.—A. Claus reports on the constitution of acroleïne, looked upon by Kolbe as an acetone, on account of its transformation by hydrogen into isopropylic acid. This Prof. Claus denies to be the case; the alcohol obtained forming no acetone by oxidation.—W. Henneberg has found a source of error in using Pettenkofer's apparatus for determining the products of respiration; the respiration of people approaching the apparatus influencing the amount of carbonic acid.—H. Schiff has found that acetic acid and oil of bitter almonds form cinnamic acid when treated with a minute quantity of HCl or $Zn\,Cl_2$. A larger quantity of these substances transforms the acid into metastyrol.—A. Oppenheim recommends the action of bibromide of copper for transforming organic iodides into bromides. With an alcoholic solution of this salt and iodide of allyle, the transformation is instantaneous, protoiodide of copper being precipitated at ordinary temperatures. An aqueous solution acts in the same way at a higher temperature. By the transformation of the bibromide into the protoiodide of copper, however, bromine is liberated, which will combine with non-saturated bromides. The method is, therefore, only applicable to saturated compounds.—C. Rammelsberg reported on isomorphous mixtures of selenium and sulphur.

May 9.—V. Meyer, in order to decide whether the hydrate of chloral is a molecular combination—thus, $C\,Cl_3 - C = O\,H + H_2O$—or whether the water enters into the atomic constitution of the body—thus, $C\,Cl_3 - C\,H\,(O\,H)_2$—has tried its action on chloride of acetyl. H_2O is thereby separated, and one molecule of chloride of acetyle takes its place. The first supposition, therefore, appears the more probable of the two.—P. Groth has entered into a long series of important and difficult researches to investigate the connection between the chemical constitution and crystalline form of organic bodies. He communicates his first results, founded on his measurement of the form of benzol during the great cold of last winter, and comparing with it the forms of benzolic derivatives, in which one or more hydrogen are replaced by O H, N O_2, or Cl. He has come to the conclusion that, by these substitutions, *the numeric relations of two axes remain intact, the third axis only increasing or decreasing with the chemical substitution* The influence thus exercised by certain elements or groups taking the place of hydrogen, he calls their *morphotropic* power. The morphotropic power of chlorine appears far greater than that of N O_2 or of O H. The morphotropic changes, however, depend likewise on the position the element or group occupies in the molecule, and on the crystallographic system of the primary substance. The author has also investigated certain combinations of naphthalene in the same sense. They bear out the law quoted above. For the conclusions drawn from these highly interesting results we must refer to the original paper.—M. Lex has found that phenol mixed with nitrite of potassium and a reducing substance (such as sugar and lime, or hydrochloric acid and zinc), and then exposed to the air, or the oxidising action of chloride of lime, gives rise to a blue colour, much like indigo, but very unstable.—A. W. Hofmann reported on the curious researches of Prof. Church on the red colouring matter of the feathers of the Turacon.—C. Rammelsberg has analysed Indian steel, or wootz, without finding in it a trace of aluminium.—M. Topsöe has analysed platinic acid and platinate of barium, to which he gives the formula: Pt O_2, 2 H_2 O and Ba Pt O_3 + 3 H_2O respectively.—M. Clemenks, by treating the impure choride of pyroracemic acid with alcohol and with ammonia, has obtained the corresponding ether and amide.—MM. Kékulé and Quinke report on some reactions of metaldehyde and of paraldehyde.—M. Czumpelik has prepared the cyanide of nitrobenzyle and of amidobenzyle, and some derivatives of cuminic and of oxycuminic acids. The same author, by introducing one atom of chlorine into cymol, and treating the compound with acetate of potassium, obtained the corresponding organic acetate. —Mr. Buchanan, from Glasgow, has studied the complex action chloride of phosphorus shows with hyposulphite of lead.

Montreal

Natural History Society, April 25.—The Rev. Dr. DeSola presiding. Dr. Smallwood read the first paper, "On some phenomena of the Solar Eclipse of August 1869." It was intended to illustrate more fully a paper which he had contributed to the *Canadian Naturalist*, referring to the rose-coloured prominences of the sun's chromosphere, and their appearance before first contact. He exhibited diagrams of the several eclipses of 1851, 1860, 1868, and 1869, which showed the various shapes of the protuberance, and referred more particularly to the large one observed during the eclipse of last August, some 30,000 miles high, which was seen in a direct line with the passage of the moon across the sun's disc. He attributed the appearances which were observable a few seconds before the first contact of the Moon with the Sun's true limb to this circumstance, and cited and illustrated the experiments of Mr. J. N. Lockyer and Janssen, in confirmation of this opinion. The remarks of the Astronomer Royal, on the causes which, up to 1861, had prevented these prominences being seen, except during a solar eclipse, were quoted from the Transactions of the British Association. The spectroscope and other optical appliances have now made it possible to examine these phenomena at any time when the sun is shining. The experiments of Lockyer and Janssen seem fully to bear out the conclusions to which Dr. Smallwood had arrived, and the lecturer ended by expressing a hope that observations made on the eclipse of next December would tend to illustrate further the somewhat unusual appearances which he had recorded.—The Acting President made some remarks on the above paper, and expressed his regret at the want of good astronomical instruments in the city.—Mr. A. S. Ritchie then read a paper entitled "Aquaria Studies, No. 1." After some preliminary remarks, the principles upon which a fresh-water aquarium should be constructed and stocked were explained in detail, and particulars were given as to how the balance between animal and vegetable life might be best maintained. The author went on to describe some of the peculiarities of the larger tenants of his own aquarium. Commencing with the fishes, the various points of interest connected with the habits of several of the smaller Canadian fresh-water fishes were dwelt upon at some length. The species described were a new Stickleback, lately described by Principal Dawson in the pages of the *Canadian Naturalist*; the Darter, a fish which has no air-bladder, and swims by jerks; the Striped Minnow, the Sun-fish, American Perch, Black Bass, Cat-fish, Pond-sucker, the Black Minnow, a species allied to the Pike; and, although not a Canadian species, the Gold-fish. Illustrations were also given of the behaviour in captivity of the Painted Turtle, the Water Newt, the Shad Frog, and the American Crayfish. In conclusion the lecturer stated that in part No. 2 of Aquaria Studies, he hoped to give descriptions of the microscopical denizens of his miniature pond.

DIARY

THURSDAY, May 26.

Society of Antiquaries, at 8.30.—Election of Fellows.
Zoological Society, at 8.30.—On Dinornis (Part xvi.), containing Notices of Internal Organs of some Species, with a Description of the Brain and some Nerves and Muscles of the Head of the Apteryx australis: Professor Owen, F.R.S.—Notes on the Anatomy of the Prongbuck (Antilocapra americana): Dr. J. Murie.—Some Remarks on the Poison Glands of the Genus Callophis: Dr. A. B. Meyer.—Notes on some Fishes from the Western Coast of India: Surgeon Francis Day.
Royal Institution, at 3.—Electricity: Prof. Tyndall.

FRIDAY, May 27.

Royal Institution, at 8.—Primitive Vegetation of the Earth: Principal Dawson.
Quekett Microscopical Society, at 8.

SATURDAY, May 28.

Royal Institution, at 3.—Comets: Prof. Grant.

MONDAY, May 30.

London Institution, at 4.—Botany: Prof. Bentley.

TUESDAY, May 31.

Anthropological Society, at 8.—On the Armenians of Southern India: Dr. John Shortt.—The Races of Morocco: J. Stirling, M.A.
Royal Institution, at 3.—Present English History: Prof. Seeley.

WEDNESDAY, June 1.

Ethnological Society, at 8.30 (at the Royal United Service Institution, Whitehall Yard).—Report on the Prehistoric Antiquities of Dartmoor: C. Spence Bate.

THURSDAY, June 2.

Royal Society, at 8.30.
Society of Antiquaries, at 8.30.
Chemical Society, at 8.—On the Platinum Ammonias: Dr. Odling.
Linnean Society, at 8.—On some New Forms of Trichopterous Insects.
Royal Institution, at 3.—Electricity: Prof. Tyndall.

BOOKS RECEIVED

English.—On the Strength of Beams, Columns, and Arches: B. Baker (E. and F. Spon).—Flint Chips, a Guide to Prehistoric Archæology: E. T. Stevens (Bell and Daldy).—The Interior of the Earth: H. P. Malet (Hodder and Stoughton.)

Foreign (through Williams and Norgate).—Palæontographica, Beiträge zur Naturgeschichte der Vorwelt; Supplement (Die Fauna der ältern Cephalopoden): R. A. Zittel.—Protozoe Helvetica: W. A. and C. F. Ooster.

THURSDAY, JUNE 2, 1870

WHENCE COME METEORITES?

M. STANISLAS MEUNIER, the *collaborateur* of M. Daubrée, at the *Jardin des Plantes*, has worked with much assiduity during the past two years at the analysis of certain of the meteorites contained in the now important collection of these bodies in Paris; and in a recent number of this journal an account was given of a view propounded in *Cosmos* by M. Meunier as an answer to the question, Whence come Meteorites?

Whether M. Meunier's theoretical conclusions are to be looked on with the same favour that we heartily accord to his practical work is what we are about to discuss.

Briefly stated, his view is, that the character of the meteorites that fall on the earth has, during the short period embraced by human history, undergone a change. He supposes that formerly—by what he deems to have been a providential arrangement for the supply of metallic iron to our earliest ancestors, ere metallurgy had become an art—the meteorites that fell were of iron. Subsequently, and in our own particular age, stony meteorites have been descending to us of what M. Meunier terms the *type commun*. We may, perhaps, more accurately describe them as fine grained mixed rocks often presenting spherular structure, and consisting of magnesian and ferro-magnesian silicates, associated with small quantities of augitic and felspathic minerals, nickeliferous iron, and ferrous monosulphide (troilite), the last two sporadically disseminated in variable amounts.

These, then, are the meteorites that are falling now. Already M. Meunier thinks he sees the beginning of a new order of meteoric falls, though he does not give a single fact to show that such is the case, in the occasional visit to our earth of what he calls "the lavas" of the type of the meteorite of Stannern (which fell 22nd May, 1808), and of the carbonaceous meteorites, like that of Cold Bokkveldt (of 13th October, 1838). The former of these two very dissimilar kinds of meteorites consists, we may state, chiefly of a mixture of augite and anorthite, with a scarcely discernible amount of nickel-iron; in the latter kind graphite and solid hydro-carbon, strange to say, are met with, mixed with enstatite or olivine. These M. Meunier tells us are to be the meteorites of the immediate future. We fail, however, to see that these are less our contemporaries than are those of the *type commun*, except, indeed, that there are fewer of them. After they have had their day, our children may begin to look out for granitoid rocks, and perhaps even for portions of stratified deposits; and if we are disposed to ask "What next?" we must push M. Meunier's hypothesis to the logical conclusion his modesty seems to shrink from, and leave it to our remoter descendants to search diligently among the meteoric falls of their time for the fossil relics of organisms that may once have flourished on a now demolished world—providentially, let us suppose, reserved till those latter days, that they may reveal the answer to that keenly debated problem which Sir David Brewster linked with the hopes of the philosopher and the faith of the Christian!

For M. Meunier supposes meteorites to be the shattered morsels of a satellite smaller than and perhaps subordinated to the moon, which has run its course and been broken up by those internal throes of volcano and earthquake that form the true "defectus solis varios lunæque labores" which are in turn, according to M. Meunier, to break up Moon, and Earth, and Sun himself.

The fragments of this satellite he believes to be now careering in every direction, retrograde as well as direct, around our world, and gradually falling into its surface; the iron masses, as possessing the greatest specific gravity, having already descended; the rest following and to follow in the order of their densities. Certainly, we may observe, *in limine*, that this satellite must have been a very minute one, or its metallic ingredient in very small proportion to its other materials, if the iron meteorites that have reached the earth in historic times represent in any considerable proportion the amount of that ingredient. And it is not very easy to see what is to bring to the earth masses of matter, however small, moving in orbits round it, unless it be the retardation caused by their coming into contact with its atmosphere; an influence that would of course act in precisely the inverse manner to that assumed by M. Meunier, as the masses of lowest specific gravity would be the first to succumb to it.

But what are M. Meunier's grounds for this hypothesis? Does he explain anomalies in the moon's motion by it? Or does he rest it on what would certainly be at least a plausible ground for linking the meteorites by some close bond of attraction and direction of motion with the earth—on the fact, namely, that over one region in India, near to the greatest mountain protuberance on our globe, the recorded falls of meteorites are more numerous than on any other spot? a fact, however, that we believe has an altogether different explanation. M. Meunier does not even hint at such arguments as these. He goes to tradition, to a fragment of Æschylus, and to such comparatively modern evidence as that of an Icelandic Saga. In the former allusion is made to the well-known stone-strewn plain of the Crau, north-west of Marseilles, which according to the ancient myth was the scene of the contest between Hercules and the Ligures, when Zeus rained down a shower of stones to aid the hero. Now, if a myth venerable four centuries before Christ has any bearing on the question, this passage would certainly seem to hint that the *grêle de galets*, which M. Meunier quotes from Bouillet's translations (in the original it is νιφάς στρογγύλων πέτρων), records a familiarity in those ancient days with falls of stones rather than of masses of iron, and certainly the quotation M. Meunier gives from a translation of the Edda might embody an allusion at least as happily to the aurora or to an eruption of Hecla as to a fall of meteorites. M. Meunier does not allude to the meteorite of Troy or of Ægospotamos or to the image of the Ephesian Artemis; and these were surely stones. So was the meteorite of Emesa, and if it be meteoric, such must be that other venerable fetish the Caaba stone. We need not perhaps discuss M. Meunier's wonderful attempt to connect by etymology the Latin *sidus* with the Greek σίδηρος, if this is what he implies by saying that σίδηρος had the double meaning of a star and of iron. But dismissing these cloudy reasonings, we may consider two other arguments brought forward by M. Meunier. One of these consists in the paucity of the number of iron meteorites that have been seen to fall as compared with that of stones of which the falls were witnessed: the proportion being only about 4 or 5 per cent. Thus in the collection at the British Museum we have 106 specimens of iron (siderites and siderolites together) indubitably meteoric, of which four only were seen to fall, while there are 179 of meteoric stones, of which only five have *not* been seen to fall. Surely, however, we have a sufficient explanation of this in the nature of the bodies themselves. The one, a mass of solid iron, besides possessing far greater permanence than a soft and porous rock permeated by small particles of readily rusting metal, would, if lying on the ground, be at once recognised by any one familiar with the metal, and would be preserved for use or as a curiosity; while the meteoric stone so found would equally naturally be neglected, unless the finder knew a meteorite as well as M. Meunier. Hence the iron meteorite is both better preserved and more surely recognised; and hence though its fall is a far rarer event in nature than that of the meteoric stone, our collections are comparatively rich in iron meteorites. That the American Continent has furnished so many meteoric irons to our collections is, no doubt, due to the ignorance of the uses of iron on the part of the ancient inhabitants of that continent, and to the comparatively unpeopled nature of the country. It is in the United States, and scattered over the plains and valleys of Mexico, or lying unrusted under the clear dry air of the Cordilleras of the Andes, that most of these iron masses have been found. They afford an ocular proof that, though after a longer or shorter time such irons must sink into a shapeless mass of oxides, yet under favourable conditions they can and do last through long generations before this destructive process is consummated. Indeed, if they do not, what becomes of M. Meunier's main argument? And if they do, the anomaly of their coming into our collections, while the stones, the fall of which has not been witnessed, are absent, does not seem so inexplicable.

M. Meunier advances another argument in support of his theory founded on the similarity of composition of certain meteorites that he has examined, and in which he recognises what he terms a stratification of different recurring varieties.

Assuming the correctness of this statement, we fail to see its logical connection with his theory. It is no new fact in the mineralogy of meteorites, whether of stone or iron, that the same minerals and combinations recur in them, and that certain of them look like chips from the same block. It is on this very account that a community of origin for those belonging to each group of them, if not indeed for the whole of even these groups themselves, has been so long suspected. But is not this a community of origin that links them not only one with another, but probably also to other bodies in space, and that by a much further reaching chain than one which would bind them down only to our tiny orb and its satellite? Indeed, the very remarkable parallelism between their constituent elements and those which have been revealed by prismatic analysis as existing in activity on the surface of the sun, gives to this question of the origin of meteorites an interest of that expectant kind which holds us, as it were, listening for the announcement of what may be the next new discovery in solar physics—some fact that may illuminate as by electric light the whole solar system, and, clearing up the mystery that surrounds the comets, the zodiacal light, the solar corona, and even our aurora, may tell us why the "fiery tears of St. Lawrence" and other meteor showers do not descend on us as νιφάδες πέτρων, and even explain the source whence the meteorites do really come. We shall then be able better to decipher the characters in which the history of the meteorites is written, a history which assuredly is engraved, though in hieroglyphic language, on these messengers from space to our world. Expectation of this kind should surely invest our reasoning with the kind of caution which befits men who, feeling in the twilight after a "quest" of this kind, are conscious that they cannot be very far off from touching it in very truth, and, as it were, with their hands. We venture to think that M. Meunier has not, on this occasion, succeeded in attaining to the object of that quest.

N. S. MASKELYNE

WHAT IS ENERGY?

II.

IN our first article it was shown that energy, or the power of doing work, is of two kinds, namely, energy due to actual motion, and that due to position. We ended by supposing that a stone shot vertically upwards had been caught at the summit of its flight and lodged on the top of a house; and this gave rise to the question, What has become of the energy of the stone? To answer this we must learn to regard energy, not as a *quality*, but rather as a *thing*.

The chemist has always taught us to regard quantity or mass of matter as unchangeable, so that amid the many bewildering transformations of form and quality which take place in the chemical world, we can always consult our balance with a certainty that *it* will not play us false. But now the physical philosopher steps in and tells us that energy is quite as unchangeable as mass, and that the conservation of both is equally complete There is, however, this difference between the two things—the same particle of matter will always retain the same mass, but it will not always retain the same energy. As a whole, energy is invariable, but it is always shifting about from particle to particle, and it is hence more difficult to grasp the conception of an invariability of energy than of an invariability of mass. For instance, the mass of our luminary always remains the same, but its energy is always getting less.

And now to return to our question,—What has become of the energy of the stone? Has this disappeared? Far from it; the energy with which the stone began its flight has no more disappeared from the universe of energy, than the coal, when we have burned it in our fire, disappears from the universe of matter. But this has taken place:—the energy has changed its form and become spent or has disappeared as energy of actual motion, in gaining for the stone a position of advantage with regard to the force of gravity.

If we study this particular instance more minutely, we shall see that during the upward flight of the stone its energy of actual motion becomes gradually changed into energy of position, while the reverse will take place during its downward flight, if we now suppose it dislodged from the top of the house. In this latter case the energy of position with which it begins its downward flight is gradually reconverted into energy of actual motion, until at last, when the stone reaches the ground, it has the same amount of velocity, and, therefore, of actual energy, which it had at first.

Let us now revert, for a moment, to the definition of energy, which means the power of doing work, and we shall see at once how we may gauge numerically the quantity of energy which the stone possesses, and in order to simplify matters, let us suppose that this stone weighs exactly one pound. If therefore, it has velocity enough to carry it up one foot, it may be said to have energy enough to do one unit of work, inasmuch as we have defined one pound raised one foot high to be one unit of work; and in like manner if it has velocity sufficient to carry it 16 feet high, it may be said to have an energy equivalent to 16 units of work or foot-pounds as those units are sometimes called. Now, if the stone be discharged upwards with an initial velocity of 32 feet per second, it will rise 16 feet high, and it has therefore an energy represented by 16. But if its initial velocity be 64 feet per second it will rise 64 feet high before it turns, and will therefore have energy represented by 64. Hence we see that by doubling the velocity the energy is quadrupled, and we might show that by tripling the velocity the energy is increased nine times. This is expressed in general terms by saying that the energy or quantity of work which a moving body can accomplish varies as the square of its velocity. This fact is well known to artillerymen, for a ball with a double velocity will penetrate much more than twice as far into an obstacle opposing its progress.

Let us now take the stone or pound-weight having an initial velocity of 64 feet per second, and consider the state of things at the precise moment when it is 48 feet high. It will at that moment have an actual velocity of 32 feet per second, which, as we have seen, will represent 16 units of work. But it started from the ground with 64 units of work in it: what therefore has become of the difference—or 48 units? Evidently it has disappeared as actual energy; but the stone, being 48 feet high, has an energy of position represented by 48 units; so that at this precise moment of its flight its actual energy (16), *plus* its energy of position (48), are together equal to the whole energy with which it started (64).

Here, then, we have no annihilation of energy, but merely the transformation of it from actual energy into that implied by position; nor have we any creation of energy when the stone is on its downward flight, but merely the re-transformation of the energy of position into the original form of actual energy.

We shall presently discuss what becomes of this actual energy after the stone has struck the ground; but, in the meantime, we would repeat our remark how intimate is the analogy between the physical and the social world. In both cases we have actual energy and energy of position, the only difference being that in the social world it is impossible to measure energy with exactness, while in the mechanical world we can gauge it with the utmost precision.

Proteus-like, this element energy is always changing its form; and hence arises the extreme difficulty of the subject, for we cannot easily retain a sufficient grasp of the ever-changing element to argue experimentally regarding it. All the varieties of physical energy may, however, be embraced under the two heads already mentioned, namely, energy of actual motion and of position. We have chosen the force of gravity, acting upon a stone shot up into the air, as our example; but there are other forces besides gravity. Thus, a watch newly wound up is in a condition of visible advantage with respect to the force of the main-spring; and as it continues to go it gradually loses this energy of position, converting it into energy of motion. A cross-bow bent is likewise in a position of advantage with respect to the spring of the bow; and when its bolt is discharged, this energy of position is converted into that of motion. Thus again, a meteor, a railway train, a mountain torrent, the wind, all represent energy of actual visible motion; while a head of water may be classed along with a stone at the top of a house as representing energy of position. The list which represents visible energy of motion and of position might be extended indefinitely; but we must remember that there are also invisible molecular motions, which do not the less exist because they are invisible.

One of the best known of these molecular energies is *radiant light and heat*—a species which can traverse space with the enormous velocity of 186,000 miles a second.

Although itself eminently silent and gentle in its action it is, nevertheless, the parent of most of the work which is done in the world, as we shall presently see when we proceed to another division of our subject. In the mean time we may state that radiant light and heat are supposed to consist of a certain undulatory motion traversing an etherial medium which pervades all space.

Now, when this radiant energy falls upon a substance, part of it is absorbed, and in the process of absorption is converted into *ordinary heat*. The undulatory motion which had previously traversed the thin ether of space has now become linked with gross palpable matter, and manifests itself in a motion which it produces in the particles of this matter. The violence of this rotatory or vortex-like motion will thus form a measure of the heat which the matter contains.

Another species of molecular energy consists of *electricity in motion*. When an electric current is moving along a wire, we have therein the progress of a power moving like light with enormous velocity, and, like light, silent in its operation. Silent, we say, if it meets with no resistance, but exceedingly formidable if it be opposed; for the awe-inspiring flash is not so much the electricity itself as the visible punishment which it has inflicted on the air for daring to impede its progress. Had there been a set of stout wires between the thunder-cloud and the earth, the fluid would have passed into the ground without disturbance.

The molecular energies which we have now described may be imagined to represent motion of some sort not perceived by the outward eye, but present nevertheless to the eye of the understanding, they may therefore be compared to the energy of a body in visible motion, or actual energy as we have termed it.

But we have also molecular energies which are more analogous to the energy of position of a stone at the top of a cliff.

For instance, two bodies near one another may be endowed with a species of energy of position due to *opposite electrical states*, in which case they have a tendency to rush together, just as a stone at the top of a cliff has a tendency to rush to the earth. If the two bodies be allowed to rush together this energy of position will be converted into that of visible motion, just as when the stone is allowed to drop from the cliff its energy of position is converted into that of visible motion.

There is finally a species of molecular energy caused by *chemical separation*. When we carry a stone to the top of a cliff, we violently separate two bodies that attract one another, and these two bodies are the earth and the stone. In like manner when we decompose carbonic acid gas into its constituents we violently separate two bodies that attract one another, and these are carbon and oxygen. When, therefore, we have obtained in a separate state two bodies, the atoms of which are prepared to rush together and combine with one another, we have at the same time obtained a kind of energy of molecular position analogous on the small scale to the energy of a stone resting upon the top of a house, or on the edge of a cliff on the large or cosmical scale.

BALFOUR STEWART

FORMS OF ANIMAL LIFE

Forms of Animal Life; being Outlines of Zoological Classification, based upon Anatomical Investigation, and illustrated by Descriptions of Specimens and of Figures. By George Rolleston, D.M., F.R.S., Linacre Professor of Anatomy and Physiology in the University of Oxford. (Oxford: Macmillan and Co., 1870; Clarendon Press Series.)

I.

THIS long-promised and hoped-for book has at last appeared, and we may say at once that it fully maintains the well-earned reputation of its learned author. It will probably be most useful to his own pupils, for whom it seems to have been originally designed; and to those students of Comparative Anatomy who teach as well as learn.

The work consist of three parts: first, an enumeration of the anatomical characters of each sub-kingdom and class, arranged in a descending order from Mammalia to Gregarinæ—a plan less useful in most respects than the reverse one which is now generally followed. Next comes a minute description of certain dissected specimens in the new Museum at Oxford; and lastly an explanation of twelve plates, most of them original, which together supply a tolerably detailed account of the anatomy of at least one specimen of almost every class. "The distinctive character of the book consists in its attempting so to combine the concrete facts of Zoötomy with the outlines of systematic classification, as to enable the student to put them for himself into their natural relations of foundation and superstructure. The foundation may be made wider, and the superstructure may have its outlines not only filled up, but even considerably altered by subsequent and more extensive labours; but the mutual relations of the one as foundation and of the other as superstructure, which this book particularly aims at illustrating, must always remain the same." (Preface, p. vi.) This is very true, and it would have been well if all systems of classification had been thus based on anatomical facts. We may even suggest that the mutual relation of the foundation and the superstructure would have been still more obvious if the anatomical had preceded the systematic parts of the present work.

We propose, however, to follow Professor Rolleston's order, and to discuss here the classification he adopts, reserving an account of the second and third parts for a future article.

The question whether a perfect Zoological classification would be merely, like a perfect Nosology, a convenient method of stating and remembering a number of concomitant variations, or whether it would represent real genealogical relations between the several groups of animals, is one which has acquired great importance since the facts adduced by Darwin and Wallace have given probability to a modified form of the old theory of evolution. Most German naturalists fully accept this hypothesis, and employ their skill in constructing genealogical trees of each class. Dr. Rolleston holds that acceptance or rejection of the modern theory of evolution will depend on the particular constitution of each mind to which it is presented: "but," he adds, "whether the general theory be accepted as a whole or not, it must be allowed that in the face on the one hand of our knowledge of the greatness of the unlikeness which may be compatible with specific identity, and on the other of our ignorance of the entirety of the geological record, the value of the special 'phylogenies' reaching far out of modern periods are [qy. is] likely to remain in the very highest degree arbitrary and problematical."

It must, however, be remembered that, apart from its truth, a scientific theory may be very valuable by the accumulation of facts and the clearing of conceptions, to which it leads. Judged by this standard, the Darwinian theory is abundantly justified, not only by the observations of its illustrious author himself, but by the mass of excellent work it has evoked from others, especially in Germany. Indeed, from the results already gained, we may almost rank the theory of Natural Selection on a level with the teleological views which led Harvey to his great discovery, or with the belief in ideal archetypes by which Goethe was led to discover the presence of a præmaxillary bone in man, the "vertebral" construction of the skull, and the true morphology of a flower.*

Again, Dr. Rolleston enumerates the many similes by which men have endeavoured to represent the system of nature, and prefers the comparison of the groups of animals to the islands of an archipelago. Most readers will probably find the metaphor of a tree with its branches more useful, especially if existing forms are regarded according to Prof. Flower's ingenious suggestion, as the transverse section of such a tree, cut off at the present stage of the world's history. But, after all, by far the most natural, convenient, and almost inevitable metaphor

* Die Descendenztheorie wird so eine neue Periode in der Geschichte der vergleichenden Anatomie beginnen. Sie wird sogar einen bedeutender en Wendepunct bezeichnen als irgend eine Theorie in dieser Wissenschaft vorher vermocht hat, denn sie greift tiefer als alle jene, und es gibt kaum Einen Theil der Morphologie, der nicht auf's Innigste von ihr berührt würde. (Gegenbaur: Grundzüge der Vergl. Anat. 1870, p. 19.)

is that of a great nation of common descent, not divided by one of the subjects into the arbitrary "provinces" of a kingdom, or "classes" of an army, but falling naturally into "alliances" which are those of blood, "families" which depend on common parentage, and "orders" which are hereditary. Now it is a great point gained to know that, probably, at least, such natural and convenient language is no metaphor at all, but strictly and literally true.

Prof. Rolleston follows Gegenbaur in elevating *Echinodermata* to the rank of a primary division, and its various orders to classes; and also in including under the head *Vermes*, not only the *Rotifera* and *Helminthes*, which, as "Scolecida," form, with Echinodermata, Prof. Huxley's Annuloid group; but the *Annulata* as well, which have been associated with the Arthropod classes by all other naturalists since Cuvier (see the long and valuable note on pp. 152-157). On the other hand, *Tunicata* and *Polyzoa* are not also placed in the same heterogeneous crowd of "Würmer," but are retained in their probably more natural position among the Mollusks. Indeed, the classes included by Dr. Rolleston under Vertebrata, Arthropoda, Mollusca, Cœlenterata, and Protozoa, are almost precisely the same as those recognised by Prof. Huxley, and generally admitted in this country. The only variation is in re-admitting Radiolaria among Rhizopods, and making "Ctenophorae" (why not Ctenophora?) a separate class, instead of an order of Anthozoa.

The "characteristics of Vertebrata" are given with the fulness and accuracy which mark the author's work. The eight closely-printed pages devoted to this section may be advantageously compared with the very short, but masterly account of the same group in Prof. Huxley's "Introduction to the Classification of Animals." Indeed, we would advise all students to read thoroughly the latter work before beginning the one under review, which would then admirably fill up the details of the London professor's sketches. At p. xxxv., it is implied that the kidney of Amphibia and most fishes answers to the permanent one of other vertebrates; its homology with the Wolffian body is, however, rightly stated at p. lxiv. We would suggest that the terms "outer" and "inner," are better than "uppermost" and "lowermost," to denote the serous and mucous layers of the germinal membrane; and at p. xl. "ventral" should replace "anterior,"—a term which confuses by mixing up the relations of human anatomy with those of general zootomy. We are not surprised that Dr. Rolleston refuses to accept Hamatocrya as a natural group of Vertebrata; he follows Prof. Huxley's division into Branchiata and Abranchiata, and of the latter into Mammalia and Sauropsida. Anammiota is a better alternative name for Branchiata than Anallantoidea; not only for euphony, but because an allantois is certainly present to some extent in certain Ichthyopsida, while its development and importance in mammals is far less than in birds and reptiles. In describing the characters of Mammalia, we notice that the author endorses Prof. Huxley's revised opinion that the malleus, not the incus, represents the quadrate bone, although the opposite is stated at p. 25 of the second part; but he appears to regard the marsupial bones as part of the pelvis, and not as mere ossifications of the internal pillar of the abdominal ring. The orders of the vertebrate classes are adopted from those given in the "Introduction to Classification" before referred to. That most of these will receive general assent there can be little doubt; but with respect to the placental classification of Mammalia, we venture to suggest some objections. In the first place the structure of the uterus and placenta is not strictly an embryonic character, but belongs to the parent organs of generation, which, in other classes, are found to be of minor importance in classification. Then it is very difficult to get accurate information as to the condition of the placenta—opportunities for observing parturition are, of course, much less frequent than for studying almost any other process—so that it will be long before we have any facts as to whole groups of animals, *e.g.*, the Sirenia. Moreover, if here opportunity is fleeting, judgment would seem to be often difficult: thus the placentation of so common a mammal as the rat was completely misunderstood by an eminent naturalist, until his account was corrected by Prof. Rolleston's own dissections. Compared with the skeleton, the teeth, or even the brain, the placenta is a far less available criterion, and far more liable to misinterpretation. But even if this were not the case, a grave objection to the placental classification remains in the fact that it necessarily excludes all fossil forms, the study of which has been so well used as a help in tracing the affinities of living animals, and by none more than Prof. Huxley himself. Lastly, judging this system by the test of concomitant variation, it is surely sufficiently condemned by compelling together animals so different as Primates and Rodentia, Orycteropus and Simia, while it separates Hyrax from Rodents and Perissodactyla, to unite it with Carnivora. The better plan we conceive is that followed by Prof. Flower in his recent lectures, to place the several orders in as natural juxtaposition as may be, and to put placental characters on the same level only as those afforded by the brain or the extremities.

In the careful description of the Mollusca which follows, Dr. Rolleston does not divide the Gasteropoda into two classes; nor does he admit the constancy of the primary flexures of the intestine, which Professor Huxley has made an important criterion of all the Molluscous series. (See pp. 58, 68, and 235.) In the *Ascidia* this question of the intestinal flexure depends upon the view taken of their great branchial sac. Dr. Rolleston does not admit Prof. Huxley's theory of its being morphologically a pharynx, but with Mr. Hancock regards it "as homologous not with a dilated pharynx, but with the branchial cavity, and the inhalent aperture to represent not the mouth, but the inhalent syphon of the Lamellibranchiata" (p. 69). If this view be accepted, it unites the Molluscoidea more closely to the Mollusca proper, and is an additional argument against their association with Vermes. The remarkable observations of Kowalewsky and Kupffer on the resemblances to vertebrate structures in the larva of Phalusia are duly noted (pp. ci. ciii.) Dr. Rolleston says of the Arthropoda that they "have frequently been classed together with more or fewer of the Vermes in one subkingdom, that of the 'Annulosa;' and whilst by such highly organised forms as the marine *Polychæta* an approximation appears to be made to certain of the less specialised of the Crustacea; or even of the Myriopoda, or the larvæ of insects, amongst the air-breathing Arthropoda; the microscopic Rotifera connect the Vermes, to which Sub-kingdom they are to be referred, very closely to the Crustacea"* (p. cvii.)

Although Gegenbaur's union of the Polyzoa and Tunicata with Vermes is not adopted, Huxley's group of Scolecida is divided into the three classes—Nematelminthes, Rotifera, and Platyelminthes. The Annulata again are divided into Annulata proper and Gephyrea. Dr. Rolleston ranks the remarkable genus *Sagitta* under the Nematelminthes (p. cxxxvii.), again following Gegenbaur, instead of placing it in a class by itself, the Chætognatha of Huxley.

We would here venture to question the advantage of the practice so generally followed by zoologists of making a separate order or even class—which generally entails at least one new name—for every aberrant genus. If *Sagitta* cannot be ranked with Annulata or Vermes, it might well stand under its generic head, or as the representation of an isolated family. In the same way we would deal with Sir John Lubbock's genus *Pauropus*, in relation to the two orders of Myriopoda, with *Hyrax* among mammals, *Archæopteryx* among birds, and *Amphioxus* among fishes. It is in vain to try to make all our classes or orders "of equal value." When natural families have been defined and grouped around a typical genus, the ordinal arrangement should, to a great extent, depend upon the number of species and other points of practical convenience. We learn nothing more of the single animal *Amphioxus lanceolatus* by a special order or sub-class, variously named by each classifier, being framed for its reception. So again we do not see the necessity of marking the distinction of *Marsupiata* and *Monotremata* from other mammals by the invention of fresh names—names which in this case have been singularly inappropriate, since several placental mammals are "didelphous," and the word "ornithodelphia" implies that birds have a uterus, and conceals the sauroid rather than ornithic affinities of Monotremata.

The description given by Professor Rolleston of the Cœlenterata is somewhat meagre, but that of Echinodermata is remarkably full, and when read in conjunction with the descriptions of *Asterias* and *Pentactes* (pp. 141-158, and 223-229, Plate x.), constitutes a valuable monograph of this complicated and interesting group of animals. Here, however, as in many other parts of the book, a few rough diagrams like those in the "Introduction to Classification," and in Prof. Greene's admirable monograph of Cœlenterata, would have been exceedingly useful, especially in explaining the more difficult points of embryology.

In treating of the Protozoa, with which the Infusoria are, we think, rightly associated, Professor Rolleston introduces a valuable disquisition upon the limits of the animal and vegetable kingdoms with the admission that "it is not rarely difficult to differentiate a unicellular organism as animal or vegetable, unless we happen to be acquainted with its past or future history" (p. clxii.). He does not admit Häckel's intermediate kingdom Protista, agreeing with almost all English naturalists in regarding *Monera* and *Protoplasta* as allied to Rhizopoda, and *Myxomycetæ* and *Flagellata* as vegetable organisms. He justly regards the chief difficulty to lie in the establishment of such statements as that animalcules as high as *Actinophrys* have at one period undoubtedly vegetable characters; but at the utmost the indeterminate groups would include very few of the organisms claimed by Prof. Häckel for his new kingdom.

In addition to the criteria usually given between animals and vegetables, it would seem that in all cases of true ovulation, the animal embryo absorbs its yelk from inside, while that of a seed is itself surrounded by the albumen; if this difference proves to be universal, it would be a remarkable foreshadowing of the mode of nourishment of adult animals and plants respectively.

* This sentence is a fair specimen of the author's compressed and parenthetical style, which sometimes reminds the reader of Lord Bacon and sometimes of S. Paul. A large insertion of brackets and dashes, of which there is scarcely one throughout the book, would often make plain the difficulties of a Thucydidean sentence, but even then only persons of great vital capacity could read the book aloud.

OUR BOOK SHELF

The Handy Book of Bees, being a Practical Treatise on their Profitable Management. By A. Pettigrew. (William Blackwood and Sons, Edinburgh and London.)

THIS book will be invaluable to the beginner in beekeeping, and will probably contain many useful hints to the more experienced. The author is one of a family of beekeepers, who have always made a large profit from their bees. He is eminently practical, and the greater part of the work consists of careful notes on the various details of successful bee management. In the descriptive parts he is also very good, but is not quite so successful when he comes to treat of some disputed points in the economy of bees. For example, he maintains the theory that the eggs of bees are of no sex, and can be made into queens, workers, or drones, as the wants of the community render necessary. In this he is opposed to all the great authorities who have studied bees; and he even gives a series of letters from Mr. Woodbury, of Exeter, on the question, which are almost conclusive as to eggs being of two sorts when laid, one producing drones only, and not capable by any subsequent treatment of producing anything else; the other capable of producing workers or queens, according to the treatment they receive. His arguments against this view are of the weakest, and he suggests an experiment, which, he says, "is within the reach of very inexperienced persons," and which would completely settle the question; and yet he writes a book in which he brings up the subject, and opposes the best authorities, without having first taken the trouble to make the experiment himself! Again, he states positively that worker-bees live nine months only—never more; yet he gives no account of how this can be ascertained, or refers to the variety of opinion that exists as to their longevity.

As an example of the valuable matter in the practical part of the work, we quote his recipe for fumigation. "A few puffs of smoke from a bit of corduroy or fustian rolled up like a candle, stupefies and terrifies bees so much that they run to escape from its power. Tobacco smoke is more powerful still, but it has a tendency to make bees dizzy, and reel like a drunken man; besides, it is far more expensive, and less handy. Old corduroy or fustian is better than new, unless the matter used to stiffen it be completely washed out. The stiffening matter won't burn. The old worn-out and castaway fustian and corduroy clothes of labouring men cannot be surpassed for the purpose of stupefying bees. Let me ask the most timid beekeeper in the country to try it. Get a piece the size of a man's hand, rolled up rather tight, and fired at one end—not to blaze, but simply to smoke. Let him now place the smoking end so close to the door of a hive that all the smoke may go in when he blows on it. After six or eight puffs have been sent into the hive, let him lift it off the board, turn it gently over upside down, so that the bees and combs stare him in the face.

By holding and moving the smoking ends of the rags over the face of the bees and blowing the smoke among them, they run helter skelter down amongst the combs far more afraid than hurt. Now he can carry the hive round the garden under his arm without being stung. Whenever the bees are likely to rise they should be dosed again. The bee-keeper will now find he has got the mastery over his bees, and can do what he likes with them. He will be able to drive them out of a hive full of combs into an empty one, and moreover shake them back, or tumble them back, or spoonful them back into the old hive or another, as men take peas from one basket to another. The smoke does not injure the health of the bees, does not stop them from work more than two or three minutes, and the use of it is so simple, easy, and efficacious, that we have no wish to find anything better for stupefying bees."

Hives, their material, size and position; their covers, boards, supers, ekes and nadirs; the times and modes of swarming bees artificially; how to feed them, and how to take the honey; how to combine separate hives, and how best to preserve them during winter, with many other details of bee-management, will be found so fully and clearly described, and with such good reasons for every step, that we think this work may do much to render profitable beekeeping far more common than it seems to be at present.

A. R. WALLACE

Malacologia del Mar Rosso. Arturo Issel. 8vo. With five lithographed plates. (Pisa, 1869.)

WE have lately read and heard much about that great undertaking, the Suez Canal, and of its being the means of facilitating the commerce of the human race in Europe and India. Something may also be said as to the interchange of the marine fauna of the Mediterranean and Red Sea, which will probably result from this artificial mode of communication. Geology teaches us that these two seas were once (in the post-tertiary or quaternary period) connected by a natural channel; for several species of shells now inhabiting the Mediterranean, and common there, occur in a fossil state throughout the Isthmus or Desert of Suez. These are:—*Arca Noæ*, *A. lactea*, var. *erythræa*, *Donax trunculus*, *Solecurtus strigilatus*, *Gastrochæna dubia*, *Patella cærulea*, *Calyptræa Chinensis*, *Nassa mutabilis*, *N. costulata*, *Murex trunculus*, var., and *Cypræa annulus*. Now it is a remarkable fact that scarcely any species in a living state are common to the Mediterranean and the Red Sea, even after making every allowance for the range of local variation. Dr. R. A. Philippi, indeed, in the second volume of his admirable work on the Mollusca of the Two Sicilies (published in 1844), gave a list of all the marine shells which he had examined in the collection made by Hemprich and Ehrenberg in the Red Sea; and of these he identified no less than 75 species as living both in the Mediterranean and the Red Sea. According to him the number of Red Sea species found by Hemprich and Ehrenberg was 408. But it now appears that these explorers collected at Alexandria also on their way home, and that by some carelessness or mischance many of the labels indicating the localities got intermixed; so that no reliance could be placed on the collection in a geographical point of view when it was examined by Philippi.

The present work gives 574 recent or living species, of which 64 are for the first time described and 34 figured. As might be expected, nearly all are tropical and belong to the Indian Ocean. Besides these, 232 fossil species are enumerated, 25 being described as new to science, and 31 figured. The author collected 191 species on the shore at Suez in the spring of 1865; 141 were collected by the Marquis G. M. Arconati in the Gulf of Akaba, as well as at Suez; public museums and private cabinets at Berlin, Paris, Pisa, Turin, and Genoa furnished additional material; while the catalogues of Ehrenberg, Rüppel, and Vaillant, with the descriptions and plates of Philippi, Reeve, Sowerby, Kiener, and others, served for comparison and reference. Professor Issel is again gone to Suez for the purpose of continuing this interesting and useful research. His figures are very good, drawn on tinted paper. All general conchologists ought to possess the work.

I may remark that one of the Red Sea species (*Cæcum annulatum*) here stated to inhabit "Aden, Indie occidentali, Irlanda, Inghilterra"—the last two localities being, on the authority of Brown, Forbes and Hanley, and Philip Carpenter—has been only found in Great Britain among the sand from bath-sponges!

It should be known that Mr. M'Andrew dredged for several months last year in the Gulf of Suez, when he made a very extensive collection of Mollusca, including a great number of then undescribed species. I hope he will soon publish his discoveries. No one is more competent to do so.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The New Natural History Museum

I AM informed that the plan of fitting a museum with cases sealed on the side facing the public galleries, alluded to in last week's NATURE, was suggested by Dr. Hooker, in an article signed "A Metropolitan Naturalist," in the *Gardener's Chronicle* for 1858, p. 749, which also contains many other good suggestions as to the requirements of the museum.

W. H. FLOWER

The "English Cyclopædia"

IN my youth I took in "The Penny Cyclopædia," in my manhood I purchased its progeny, "The English Cyclopædia," and now, in comparative old age, I have acquired two supplementary volumes to the latter; and I have never had reason to complain of any of these books, until the supplement to the Natural History division appeared a month or two ago. This supplement embraces a period of sixteen years, from 1854 to 1870, during which, probably, more good scientific work has been accomplished than in any preceding half-century. Many subjects on which I expected to find important articles are passed over without a reference, and others are, as I shall endeavour to show, treated of in a most imperfect and unsatisfactory manner.

I looked in vain for articles on (1) *Acclimatisation*, (2) *Ants*, (on which Bates, Lespes, Lincecum, Norton, F. Smith, Sumichrast, and many others have written since 1854), (3) *Axolotl* (whose remarkable metamorphoses have been studied by Dumeril and others), (4) *Cephalopoda* (on which much has been written since the Cyclopædia article appeared, when the Hectocotylus had not become a subject of discussion), (5) *Darwinism*, (6) *Deep-sea Dredging*, (7) *Dimorphism in the Animal Kingdom*, (8) *Eophyton*, (9) *Eozoon*, (10) *Eugerion* (a fossil insect that from its puzzling form has been compared with the Archæopteryx), (11) *Fungous Origin of Diseases*, the cholera-fungus, scarlatina-fungus, ague-fungus, the fungi in skin-diseases, &c., and (12) *Hyalonema* (on which several articles holding the most opposite views have lately appeared); (13) *Hybridity in animals and plants* (on which Broca, Masters and others have written elaborate works, and on which, as in the case of rabbits and hares, many remarkable experiments have been made), (14) *Mimicry in the Animal Kingdom*, (15) *Monera*, (16) *Ornithoscelida*, (17) *Parthenogenesis* (on which, during the last sixteen years, there have been published Siebold's "True Parthenogenesis in Lepidoptera and Bees," Owen "On Parthenogenesis," Leuckart "On the recognition of Parthenogenesis in Insects," De Quatrefages' "Metamorphoses of Man and the lower Animals," and the contributions of Huxley and Lubbock to Transactions of the Linnean Society and to the Philosophical

Transactions, besides numerous articles on special cases of Parthenogenesis in certain gall-flies, solitary wasps, spiders, and mites), (18) *Protista*, (19) *Protoplasm*, (20) *Rhizocrinus*, which sent forth our late deep-sea dredging expeditions, (21) *Sauroids* and *Sauropsida*, (22) *Sphegidæ* (insects whose marvellous instincts have been described by Lespes and other observers), and (23) *Vivisection* and its results.

A few of these subjects are discussed in articles devoted to more general matters; for example, (8) is noticed, but not figured or even systematically described, under *Foraminifera, Laurentian Formations*, and *Palæontology*, and (9) is referred to in the last-named article; (12) is mentioned in *Spongiadæ*, and more fully described, but not figured, in *Alcyonaria*; (17) is alluded to, in so far as the researches of Huxley and Lubbock go, in the article *Aphis*; (19) is noticed under *Cells*; and (21) *Sauropsida* is defined in the article on *Birds*.

Cross references, which, like illustrations, have been far too scantily employed in these volumes, would have partly removed this source of complaint, as for example *Sauropsida* [Birds, E.C.S.]

On the following subjects our knowledge has not been brought up to what can with every allowance, be called a recent date:—(1) *Aerolites*, latest reference 1861, and no bibliography; (2) *Alca*, latest reference 1861; (3) *Annelida* contains no reference to Claparède's appalling criticism on De Quatrefages' researches; (4) *Archæopteryx* has no reference to Huxley's papers; (4) *Blood* contains no reference to late researches on the structure of the corpuscles, to the occurrence of *Protagon* in them, or to the remarkable colour-test for blood, discovered by Dr. Day of Geelong, which has succeeded in detecting old blood spots, when even spectrum analysis in the hands of its great master, Mr. Sorby, has failed; and Dr. Richardson is stated to hold the opinion that the fibrin is held in solution in the body by ammonia, although it is well known that, with a moral courage which cannot be sufficiently commended, he publicly (at a meeting of the British Association some years ago) renounced that opinion as soon as he found it was untenable; (5) *Birds of Paradise* would have been a more satisfactory article if it had had the benefit of Mr. Wallace's supervision; (6) *Foraminifera* would have been all the better if the writer had been acquainted with Häckel's splendid monograph on the *Radiolaria*; (7) *Nervous System* is perhaps the most imperfect article in the whole volume. It contains no reference to the labours of Gratiolet, Lockart Clarke, Brown-Sequard, Claude Bernard, Robin, Philippeaux, or Vulpian on the minute structure and the physiology of the nerves, while the chemistry of the brain is discussed without a reference to Protagon or Neurine. The synthetical formation of the latter is surely of sufficient interest to deserve notice.

Regard for the value of space in your columns alone prevents me from prolonging the list of imperfect articles.

The English Cyclopædia is, as I presume everyone will admit, intended for "all sorts and conditions of men," for "women labouring with child" (if we use the phrase in the same sense as a German governess, who is said to have expatiated to a popular bishop on the comprehensiveness of a church-service that did not even overlook the daily cares of those who devoted themselves to the duties of early education), and even for children; at all events I read the "Penny" with great pleasure as a boy. Hence it should be a source of knowledge from which we might expect to find information in all cases of ordinary difficulty. To decide how far this assumption is correct, I put it to the test in the following way:—I read Huxley's splendid address "On the recent progress of Palæontology" which lately appeared in your columns, and the "Report on a Close Time for Birds" in the last volume of the British Association Reports. I freely admit that I am not learned in Natural History; but as an old country doctor, I probably picked up quite as much knowledge in my youth, as the average class of "Cyclopædia" readers. None of the following terms taken from Huxley's address are to be found either in the Index to the Cyclopædia, or in the Supplement:—*Amphycion, Anchitherium, Anthracosaurus, Artiodactyle, Cainotherium, Chœropotamus, Coccoliths, Coccospheres, Compsognathus, Coryphodon, Dicynodes, Didelphia, Dinosauria, Discoliths, Elasmobranchs, Eophyton, Eozoon, Evolution, Galeosaurus, Globigerinæ, Hipparion, Hipparitherium, Homotaxis, Hyænictis, Hyenoartos, Hyopotamus, Hyracotherium, Ictitherium, Mesopithecus, Microlestes, Monadelphia, Omalodotherium, Ornithodelphia, Ornithoscelida, Orycteropus, Perissodactyle, Phascolotherium, Pliolophus, Pterosauria, Sauropsida, Stereognathus, Typotherium.*

I will not go further into the "Close Time" Report than to state that I learn from it the important fact that owls eat, *inter alia*, "*Arvicolæ, Crocidura, Crossopi, Hypudæi, Sorices*, shrews and voles." I look in vain for all these inviting edibles, and I find only *Hypudæus* in the Cyclopædia, and what benefit do I derive from my search? Only that *Hypudæus* is sometimes spelt *Hipudæus*. A learned friend, who is ever ready and able to remove difficulties from the paths of his weaker brethren—the genial guardian of Kent's Cavern—suggested that it was something in the mouse or rat line, and so I turned to *Muridæ*, where I found the required information regarding that animal and the voles.

It is not for the purpose of depreciating the Supplement to the English Cyclopædia that I have noticed the above omissions and deficiencies, but with the object of pointing out how they may still be remedied. The Supplement has evidently been drawn up without any editorial care. Let a duly-qualified editor obtain a list of *desiderata* from some botanist, geologist, and zoologist of eminence; and let him fix upon the articles that he deems the most important, and give them to qualified writers. Let him attend duly to the compilation of bibliographies of the most important subjects, and let him increase to an enormous extent the amount of cross references. The article *Muridæ*, from which I exhumed *Hypudæus*, would probably yield fifty references.

A few subjects—as birds and hydrozoa—are fairly supplemented. Why should not similar articles be given us on the progress, during the last sixteen years, of our knowledge of the crustaceans, insects, fishes, reptiles, &c.? An additional supplement, such as I have here suggested, would probably not occupy more than 100 pages.

NEMO

South Devon

ADMIRAL MANNERS

ADMIRAL RUSSELL HENRY MANNERS was born in London on the 31st of January, 1800, entered the Royal Naval College the 6th of May, 1813, and embarked March the 6th, 1816, as a volunteer on board the *Minden*, 74, Captain Paterson, in which, after assisting at the bombardment of Algiers, he proceeded to the East Indies, where he served under the flag of Sir Richard King, until nominated midshipman, the 1st of July, 1818, to the *Orlando*, 36, commanded by Captain John Clavell, with whom, in 1819, he returned to England on the *Malabar*, 74. After an intermediate employment on the Channel and West India stations in the *Spartan* and *Pyramus* frigates under Captains William Furlong Wise and Francis Newcombe, he became, the 29th of July, 1822, Acting Lieutenant of the *Tyne*, 26, Captain John Edward Walcot, to which vessel the Admiralty confirmed him the 19th of October following. In May 1823, he rejoined the *Pyramus*, still commanded by Captain Newcombe, under whom he continued until he obtained his promotion on the 16th of August, 1825. His last appointment was on the 21st of October, 1827, to the command of the *Britomart*, 10. The *Britomart* was first employed and intended for the Channel service under the order of the Commander-in-Chief, the Earl of Northesk, at Plymouth. She accompanied the squadron of ships escorting Don Miguel to Lisbon in the early part of 1828. In consequence of the revolution that followed in Portugal on Don Miguel declaring himself absolute, the *Britomart* was stationed at and off Oporto to watch the British interests there. The Constitutional party, failing to restore the Constitution against the usurped position of Don Miguel, the British Government withdrew her Minister from Lisbon, leaving the British interests in the hands of the Consul only, and Capt. Manners was selected to be in readiness to support him in case of need by keeping in sight of signals from Lisbon as long as the safety of the vessel permitted, but not to anchor within any Portuguese port unless absolutely necessary. This involved a long and vigilant cruising off and on the coast for about eight months, and through the whole of the winter. The only place communicated with during that time was Gibraltar, and then only to receive a supply of provisions and water from the dockyard. The yellow fever unfortunately breaking out at Gibraltar just before going there for this object, no communication could be had with the town, and the stay was confined to from twenty-four to forty-eight hours. The zeal and ability with which this service was carried out by Capt. Manners, as witnessed by Sir George Sartorius, there in command of the Portuguese Constitutional Squadron, and under whose orders in some degree the *Britomart* was placed, led to Capt Manners receiving his Post-rank on the 4th of March, 1829. He retired from active service in March 1849, became Rear-Admiral in July 1855, Vice-Admiral in April 1862, and Admiral in September 1865.

Admiral Manners was the only child of the late Mr. Russell Manners, M.P., and married in 1834 Louisa Jane, daughter of Count de Noé, Peer of France, who survives him, and by whom he has two sons and a daughter.

From the time he attained his Post-rank to the time of his death he devoted himself to scientific pursuits. He was elected a member of the Royal Astronomical Society in 1836. At a very early period he took an active interest in its administration, and after being on the Council for some time, was elected one of the honorary secretaries in February 1848, an office which he filled until 1858, when he accepted that of Foreign Secretary. This was a post for which his knowledge of foreign languages and his position in society peculiarly fitted him, and during his tenure of office he formed by active correspondence a connecting link between English and foreign astronomers. He was much esteemed abroad, so much so indeed that one of the presidents, in asking Admiral Manners to transmit one of the Society's medals to a foreign recipient, deemed it just to preface his remarks with the following well-deserved compliment :—

"Admiral Manners,—It has been my good fortune to visit the majority of European Observatories, and to make the acquaintance of their directors and other gentlemen connected with them, and it has in consequence become known to me how high in their esteem our Foreign Secretary stands. Your urbanity and promptitude in carrying out our foreign business has indeed become proverbial."

Admiral Manners was, on more than one occasion, asked to accept the chair of President, which, after some hesitation, he consented to do, and he was elected to that position in 1868. None of his predecessors was more highly esteemed by the Fellows of the Society, and no one filled the chair more admirably than he did. His mathematical attainments were considerable, more so than one might be apt to infer from his quiet demeanour. He was well versed in the astronomical literature of the day, and took a deep interest in the progress of astronomical science, both in England and on the Continent; and his active influence was always available for the promotion of any object connected with it.

On presenting the gold medal of the Society to Mr. Stone, first assistant of the Royal Observatory, Greenwich, Admiral Manners delivered a most able and exhaustive summary of that able astronomer's labours, and evinced a complete knowledge of the history of the solar parallax, for the investigation of which the medal was mainly awarded. Illness overtook him before he could complete his second year of office, and he was compelled to forego the gratification of delivering the address to M. Delaunay for his researches on the lunar theory; but he made it a point of duty and pleasure to receive M. Delaunay at his house, and although he was compelled to delegate to the friendly hand of Prof. Adams the drawing up of the address, yet he read and approved of what was written before it was delivered.

Admiral Manners in all his relations was a pure-minded, courteous, and sympathetic man, and in the fullest sense of the word a gentleman.

THE PRIMITIVE VEGETATION OF THE EARTH

TWENTY years ago scarcely anything was known, even to those engaged in the study of vegetable fossils, of a land flora older than the great coal-formation. In 1860, Goeppert, in his Memoir on the plants of the Silurian, Devonian, and Lower Carboniferous, mentions only one land plant, and this of doubtful character, in the Lower Devonian. In the Middle Devonian he knew but one species; in the Upper Devonian he enumerated fifty-seven. Most of these were European, but he included also such American species as were known to him. The paper of the writer on the Land Plants of Gaspé was published in 1859, but had not reached Goeppert at the time when his memoir was written. This, with some other descriptions of American Devonian plants not in his possession, might have added ten or twelve species, some of them Lower Devonian, to his list. In the ten years from 1860 to the present time, the writer has been able to raise the Devonian flora of Eastern North America to 121 species, and reckoning those of Europe at half that number, we now have at least 180 species of land plants from the Devonian, besides a few from the Upper Silurian. We thus have presented to our view a flora older than that of the Carboniferous period, and, in many respects, distinct from it; and in connection with which many interesting geological and botanical questions arise.

Geologists are aware that in passing backward in geological time from the modern to the Palæozoic period, we lose, as dominant members of the vegetable kingdom, first, the higher phænogamous plants, whether exogenous or endogenous; and that, in the Mesozoic period, the Acrogens, or higher cryptogams, represented by Ferns, Club-mosses, and Equiseta, share the world with the Gymnosperms, represented by the Pines and Cycads, while the higher phænogams on the one hand, and the lower cryptogams on the other, are excluded. Hence, the Mesozoic age has been called that of Gymnosperms, while the Palæozoic is that of Acrogens. These names are not, however, absolutely accurate, as we shall see that one of the highest forms of modern vegetation can be traced back into the Devonian; though the terms are undoubtedly useful, as indicating the prevalence of the types above mentioned, in a degree not now observed, and a corresponding rarity of those forms which constitute our prevalent modern vegetation.

It is my present object shortly to sketch the more recent facts of Devonian and Upper Silurian Botany, and to refer to a few of the general truths which they teach. The rocks called Devonian in Europe being on the horizon of the Erie division of the American geologists, which are much more fully developed than their representatives on the Eastern Continent, I shall use the term *Erian* as equivalent to Devonian, understanding by both that long and important geological age intervening between the close of the Upper Silurian and the beginning of the Carboniferous.

Just as in Europe the rocks of this period present a twofold aspect, being in some places of the character of a deposit of "Old Red Sandstone," and in others indicating deeper water, or more properly marine conditions, so in America, on a greater scale, they have two characters of development. In the great and typical *Erian* area, extending for 700 miles to the westward of the Apalachian chain of mountains, these rocks, sometimes attaining to a thickness of 15,000 feet, include extensive marine deposits; and except in their north-eastern border are not rich in fossil plants. In the smaller north-eastern area, on the other hand, lying to the eastward of the Apalachian range, they consist wholly of sandstones and shales, and are rich in plant remains while poor in marine fossils. Hence it is the Devonian of Gaspé, of New Brunswick, and of Maine, with that of eastern New York, which have chiefly afforded the plants to be described below; and it is exclusively in these areas that we find underclays with roots, or true fossil soils. Most of the localities of fossil plants in the districts above mentioned have been visited, and their plants studied *in situ* by the writer. The Gaspé sandstones were first studied and carefully measured and mapped by Sir W. E. Logan. The Devonian beds of St. John's, New Brunswick, have been thoroughly examined and illustrated by Prof. Hartt and Mr. Matthews, and those of Perry by Prof. Jackson, Prof. Rogers, and Mr. Hitchcock. Prof. Hall, of the Survey of New York, has kindly communicated to me the plants found in that State, and Prof. Newberry has contributed some facts and specimens illustrative of those of Ohio.

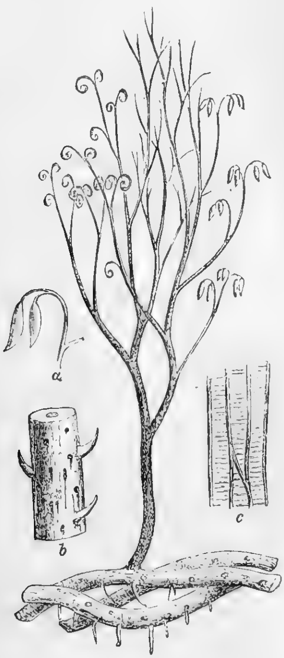

FIG. 1.—*Psilophyton princeps*—the oldest known plant of America, restored. (*a*), Fruit, natural size; (*b*), Stem, natural size; (*c*), Scalariform tissue of the axis, highly magnified. In the restoration one side is represented in vernation, and the other in fruit.

In the Sandstone cliffs of Gaspé Bay, Sir W. E. Logan recognised in 1843 the presence of great numbers of apparent roots in some of the shales and fine sandstones. These roots had evidently penetrated the beds in a living state, so that the root-beds were true fossil soils, which, after supporting vegetation, became submerged and covered with new beds of sediment. This must have occurred again and again in the process of the formation of the 4,000 feet of Gaspé sandstone. The true nature of the plants of these fossil soils I had subsequently good opportunities of investigating, and the most important results, in the discovery of the plants of my genus *Psilophyton*, are embodied in the restoration of *P. princeps* in Fig. 1. This remarkable plant, the oldest land plant known in America, since it extends through the Upper Silurian as well as the Devonian, presents a creeping horizontal rhizome or root-stock, from the upper side of which were given off slender branching stems, sometimes bearing rudimentary leaves, and crowned, when mature, with groups of gracefully nodding oval spore-cases. The root-stocks must in many cases have matted the soils in which they grew into a dense mass of vegetable matter, and in some places they accumulated to a sufficient extent to form layers of coaly matter, one of which on the south side of Gaspé Bay is as much as three inches in thickness, and is the oldest coal known in America. More usually the root-beds consist of hardened clay or fine sandstone filled with a complicated net-work or with parallel bands of rhizomes more or less flattened and in various states of preservation. In all probability these beds were originally swampy soils. From the surface of such a root-bed there arose into the air countless numbers of slender but somewhat woody stems, forming a dense mass of vegetation three or four feet in height. The stems, when young or barren, were more or less sparsely clothed with thick, short, pointed leaves, which, from the manner in which they penetrate the stone, must have been very rigid. At their extremities the stems were divided into slender branches, and these when young were curled in a crosier-like or circinate manner. When mature they bore at the ends of small branchlets pairs of oval sacs or spore-cases. The rhizomes when well preserved show minute markings, apparently indicating hairs or scales, and also round areoles with central spots, like those of Stigmaria, but not regularly arranged. These curious plants are unlike anything in the actual world. I have compared their fructification with that of the Pilulariæ or Pillworts, a comparison which has also occurred to Dr. Hooker. On the other hand, this fructification is borne in a totally different manner from that of Pilularia, and in this respect rather resembles some ferns; and the young stems by themselves would be referred without hesitation to Lycopodiaceæ. In short, Psilophyton is a generalised plant, presenting characters not combined in the modern world, and, perhaps illustrating what seems to be a general law of creation, that in the earlier periods low forms assumed characteristics subsequently confined to higher grades of being.

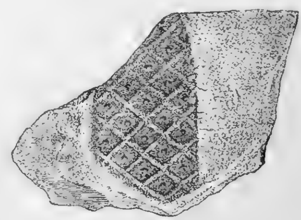

FIG. 2.—*Leptophleum rhombicum*—a Lycopodiaceous tree of the Devonian.

A second species of Psilophyton (*P. robustius*), also abundant at Gaspé, shows stouter stems than the former, more abundantly branching and with smaller leaves, often quite rudimentary. Its spore-cases are also of different form and borne in dense clusters on the sides of the stem. Masses of very slender branching filaments appear to indicate a third species (*P. elegans*) which is also found in the Devonian of St. John, New Brunswick. These species of Psilophyton occur both in the lower and middle Devonian, and, as will be mentioned in the sequel, they extend also into the Upper Silurian.

Decorticated and flattened stems of Psilophyton cannot be readily recognised, and except when their internal structure has been preserved, might be mistaken for algæ, a mistake which I believe has in some instances been made. Specimens of the barren stems (*var. ornatum*) might readily be referred to the genius *Lycopodites*.

Another genus of generalised type is that named by Haughton *Cyclostigma*. As found at Gaspé it presents slender stems with rounded scars, placed either spirally or in transverse rows, and giving origin to long rigid leaves. It had a slender axis of scalariform vessels, and fructification of the form of elongated spikes or strobiles is found with it. In many respects these plants resembled Psilophyton, and their affinities were distinctly Lycopodiaceous. Specimens from Ireland, in the Museum of the Geological Society, kindly shown to me by Mr. Etheridge, appear to show that in that country these plants attained the dimensions of trees, and had roots of the nature of Stigmaria. Mr. Carruthers has even suggested that they may be allied to *Syringodendron*, a group of Carboniferous trees connected with the *Sigillariæ*.

The genus *Lycopodites* is represented by a trailing species, bearing numerous oval strobiles (*L. Richardsoni*), a species quite close to many modern club-mosses (*L. Matthewi*), and a remakable pinnate form (*L. Vanuxemii*), which, though provisionally placed here, has been variously conjectured to resemble Ferns, Cycads, Algæ, and Graptolites. But the most remarkable Lycopodiaceous plants are the gigantic arboreal *Lepidodendra*, plants

FIG. 3.—*Cyclopteris* (*Archæopteris*) *Jacksoni*—a Devonian Fern, the American representative of *C. Hibernicus*.

which, while they begin in the Middle Devonian, become eminently expanded in numbers and magnitude in the Carboniferous. The common species in Eastern America (*L. Gaspianum*) was of slender and delicate form, very elegant, but probably not of large size. In the same family I would place my new genus *Leptophleum*, a portion of whose curiously-marked bark is represented in Fig. 2.

The *Calamites*, afterwards so largely developed in the Carboniferous, and to be replaced by true Equiseta in the Trias, make their first appearance in a large species (*C. inornatum*) in the Lower Devonian, and are represented in the middle and upper parts of the system by two other species, which extend upward into the Carboniferous. They are also represented in the Devonian of Germany and of Devonshire. The peculiar type indicated by the internal casts known as *Calamodendron* is likewise found in the Devonian.

More beautiful plants were the *Asterophyllites*, with more slender and widely branching stems, and broader leaves borne in whorls upon their branches. These plants have been confounded with leaves of Calamites, from which, however, they differ in form and nervation, and in the want of the oblique interrupted lines common to the true leaves of Calamites and to the branchlets of Equisetum. The Asterophyllites, and with them a species of *Sphenophyllum*, appear in the Middle Devonian.

No plants of the modern world are more beautiful in point of foliage than the Ferns, and of these a great number of species occur in the Middle and Upper Devonian. I must refer for details to my more full memoirs on the subject, and in the present paper shall content myself with a few general statements. Some of the generic forms of the Devonian, and perhaps a few of the species, extend into the Carboniferous; others are peculiar to the Devonian; and among these, forms allied to the modern Hymenophyllum and Trichomanes appear to prevail. One remarkable type, *Cyclopteris* (*Archæopteris*) *Hibernicus*, with its American allies, *C. Jacksoni*, &c., extends in the Upper Devonian over both continents, yet is wanting in the Carboniferous. Tree ferns also existed in the Devonian. Two species have been found by Dr. Newberry in Ohio, and remarkable erect trunks have been obtained by Professor Hall from Gilboa, in the State of New York. The latter are surrounded by aerial roots, and thus belong to the genus *Psaronius;* a genus which, however, must be artificial, since in modern tree ferns aerial roots often clothe the lower part of the stems while absent from the upper part. The only indication as yet of a tree fern in the Old World is the *Caulopteris Peachii*, of Salter, from the Old Red of Scotland. It is further remarkable that the ferns of the genus Archæopteris are much more large and luxuriant in Ireland than in America, and that in both regions they characterise the upper member of the system.

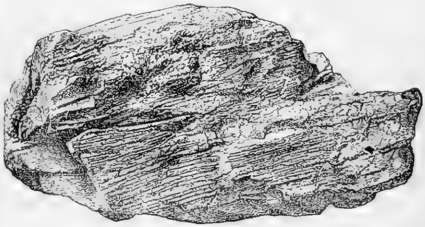

FIG. 4.—*Prototaxites Logani*—the oldest known tree. (Fragment of the trunk, much reduced.)

Of the plants of the Palæozoic world, none are more mysterious than those known to us by the name *Sigillariæ*, and distinguished by the arrangement of their leaves in vertical series, on stems and branches often ribbed longitudinally, and by the possession of those remarkable roots furnished with rootlets regularly articulated and spirally arranged, the Stigmariæ. It seems evident that this group of plants included numerous species, differing from each other both in form and structure. Still, as a whole, they present very characteristic forms dissimilar from those of their contemporaries, and still more unlike anything now living. I believe that many of them were Gymnosperms, or at the least, Acrogens with stems as complicated as those of Gymnosperms. In the Carboniferous period these plants have a close connection with the occurrence of coal. Nearly every bed of this mineral has under it a "Stigmaria underclay," which is a fossil soil on which a forest of Sigillariæ has grown, and the remains of these trees are very abundant in the coal and the accompanying beds. Hence the Sigillariæ of the coal-period are regarded as the plants most important in the accumulation of coal. In the Devonian, as far as we yet know, they did not attain to this utility, and in the lower part of the system at least, the rhizomata of Psilophyton seem to have occupied the place afterwards held by the Stigmariæ. In connection with this, it is to be remarked that the Sigillariæ of the Erian period seem to have been few, and of small dimensions in comparison with those of the coal.

Rising still higher in the vegetable kingdom, and arriving at unquestionable Gymnosperms, we find in the Devonian of Eastern America, and also, I believe, in that of Scotland and Germany, trunks which may be referred to Coniferæ. In the Middle and Upper Devonian these present the structure of modern Araucarian pines, or that modification of it belonging to the Carboniferous trees of the genus *Dadoxylon*. In the Lower Devonian we have what seems to be a simplification of the Coniferous structure, in the cylindrical wood-cells, marked only with spiral threads, found in the genus *Prototaxites*. These trees are very abundant as drift trunks in the Lower Devonian, down almost to its bottom beds, and sometimes attain to a diameter of three feet. Though of a structure so lax that it is comparable only with the youngest stems of ordinary Coniferæ, these trees must have been durable, and they are furnished both with medullary rays and rings of annual growth. Unfortunately we know nothing of their foliage or fruit. Fig. 4 represents a fragment of the wood of one of these trees, mineralised by infiltration of the tissues with silica, so that the structure is preserved.

But for one little fragment of wood, we should have had no indication of the existence in the Erian of any trees of higher organisation than the Conifers. This fragment, found by Professor Hall at Eighteen-mile Creek, Lake Erie, has the dotted vessels characteristic of ordinary Exogens, and unquestionably indicates a plant of the highest kind of organisation. Until confirmed by other facts, this discovery may be received with doubt, but I believe it can be relied on.

Our knowledge of the flora of the Upper Silurian is at present nearly in the same state with that of the Middle and Lower Devonian ten years ago. I know in the Upper Silurian of Canada but two species of *Psilophyton*, both apparently identical with Devonian forms. In England, besides the spore-cases known by the generic name *Pachytheca*, there exist in the collections of the Geological Survey fragments of wood and bark which I believe indicate two additional species. In Germany three or four species are known in rocks of this age. All of these plants appear to be Acrogens allied to Lycopodiaceæ. That these few species constitute the whole flora of the Upper Silurian we can scarcely believe. They occur in marine formations, and were probably drifted far from the somewhat limited land-surfaces which existed in the explored parts of the Upper Silurian areas. When we obtain access to deposits of this age formed in shallows or estuaries, we may hope to find a flora of greater richness; and, judging from present indications, not dissimilar from that of the Lower Devonian.

With the exception of some remains which I believe to be of very doubtful character, the Lower Silurian has as yet afforded no remains of land plants, and in North America, at least, this is very significant, inasmuch as we have, in the Potsdam sandstone, extensive sandy flats of this period, in which we might expect to find drifted trunks of trees, if such had existed. But the search is not hopeless, and we may yet find some estuary deposit on the margin of the ancient Laurentian continent, in whose beds the plants of that old land may occur.

Lastly, for reasons stated in a paper lately published in the Proceedings of the Geological Society, I believe that the extensive deposits of graphite, which exist in the Laurentian of Canada, are of vegetable origin, and possibly in part produced by land plants, as yet altogether unknown to us. If the Palæozoic was the age of Acrogens, the Eozoic may have been that of Anophytes and Thallophytes. Its plants may have consisted of gigantic mosses and lichens, presenting us with a phase of vegetable existence bearing the same relation to that of the Palæozoic, which the latter bears to that of more modern periods. But there is another and a more startling possibility, that the Laurentian may have been the period when vegetable life culminated on our planet, and existed in its highest and grandest forms, before it was brought into subordination to the higher life of the animal. The solution of these questions belongs to the future of geology, and opens up avenues not merely for speculation but also for practical work.

The above must be regarded as merely a sketch of the present aspect of the subject to which it relates. Details must be sought elsewhere. J. W. DAWSON

NOTES

THE Royal Commission on Scientific Instruction and the Advancement of Science has already begun work. A second meeting was held on the 31st ult. at Devonshire House. Present: The Duke of Devonshire, K.G., chairman; the Marquis of Lansdowne; Sir J. Lubbock, Bart., M.P., F.R.S.; Sir J. P. Kay Shuttleworth, Bart.; Mr. B. Samuelson, M.P.; Dr. Sharpey, Sec. R.S.; Professor Huxley, F.R.S.; Dr. W. A. Miller, Treas. R.S.; and the secretary, Mr. J. Norman Lockyer, F.R.S.

A MEETING of the Syndicate appointed to consider the ways and means of establishing a Chair of Experimental Physics at Cambridge was held on Tuesday last.

WE may remind our Astronomical readers that the Visitation of the Royal Observatory at Greenwich takes place at 3 P.M. on Saturday.

THE annual meeting for the election of Fellows into the Royal Society was held this morning.

THE Geographical Society of Paris has bestowed a well-earned honour on our countryman, Mr. Alfred R. Wallace, by awarding him one of their gold medals for his researches in the Malay Archipelago.

AT the meeting of the French Academy, held on the 23rd ult., the following list of candidates for the place vacant by the death of Professor Magnus was presented by the Secret Committee:—1, Mr. Joule, 2, MM. Ångström, Billet, Dove, Grove, Henry, Jacobi, Lloyd, Riess, Stokes, Tyndall, Volpicelli, and Sir William Thomson.

THE Gresham lectures for the present week at the Gresham College, Basinghall Street, are by Dr. Symes Thompson, on the 2nd, 3rd, and 4th of June, at 7 P.M., on "The Epidemics of the Middle Ages," on "Sedatives," and on "Narcotics." They are free to the public, and will be illustrated with diagrams, tables, and chemical experiments.

THE municipal administration of Paris has decided on publishing a series of documents on the history of the capital. The commission appointed for this purpose has placed at the head of its programme a sketch of the pre-historic epochs, and has entrusted this labour to M. Belgrand, who is well known in the scientific world by his important works on the basin of Paris. In presenting to the Academy a *résumé* of his work, he divides it into four parts—the diluvian epoch, the great water-courses of the age of stone, the history of the peat-mosses, and the palæontological history of the basin of the Seine during the quaternary epoch. Our Common Council of London has a splendid opportunity of distinguishing itself in the same way; is it too much to expect of such an august body?

WE perceive with great pleasure that the Radcliffe Library at Oxford is being adapted more completely to the wants of students of science. Students in any department of natural knowledge, who need scientific works, maps, or plans which they do not find in the library, are invited to record their wants in a book kept for the purpose. There is a standard microscope, by Powell and Lealand, attached to the library, for the comparison of objects with the illustrated works of the library.

THE Royal Dublin Society have commissioned Mr. Catterson Smith to paint a portrait of Dr. Joly, to be placed in their library. It will be remembered that Dr. Joly presented the Royal Dublin Society with a large and valuable library of modern books. The society already possessed a library of works on Science and Fine Arts, which, however, was very deficient in works of modern literature. It will now, with the addition of the Joly library, be one of the most useful public libraries in Great Britain and Ireland.

THE Surgical Society of Ireland gave a grand *conversazione* to its members and to the medical men of Dublin on Tuesday, the 24th ult. His Excellency the Lord Lieutenant was present. The *conversazione* was held in the Royal College of Surgeons. The small museum of the college was lit up, and looked uncommonly well. A series of interesting microscopical objects were exhibited by Dr. Barker, Mr. William Archer, Rev. Eugene O'Meara, and others.

M. DE CALIGNY called the attention of the French Academy, at its meeting of the 16th of May, to two prizes founded in 1867 by the Marquis d'Ourches, for the indications of the means of preventing people from being buried alive. The first is a prize of 20,000 frs. for the discovery of a simple method of recognising with certainty the signs of actual death. This method must be adapted to the capacities of the most ignorant. The second, a prize of 5,000 frs., is for the discovery of a means of recognising death by means of electricity or galvanism, or by some other process requiring knowledge for its application. These prizes are to be decided by the Imperial Academy of Medicine, within five years from the 22nd April, 1868.

ONE of the best signs of the times we have seen lately is the third annual report of the Rugby School Natural History Society for 1869, as giving satisfactory evidence of the interest taken in natural science by at all events a few Rugbeians. The botanical report for 1869 records the dates of flowering of 340 plants, which seem to have been carefully observed for three successive years, and a few new localities or plants new to the neighbourhood. We find also a thoroughly Darwinian paper by Mr. J. M. Wilson on "A remarkable instance of protective mimicry among the *Lepidoptera*;" the well-known example of the female of *Papilio Merope*, with an illustration; one on "English Snakes and the Blind-worm," by Mr. N. Masterman, secretary of the society; an elaborate account by Mr. J. M. Wilson of the "Drifts, Gravels, and Alluvial Soils of Rugby and its neighbourhood," illustrated by some carefully-executed drawings; a paper by the Rev. T. N. Hutchinson "On Spectrum Analysis and what it has done;" and one on "Norway," by Mr. Sedgwick. Other papers not reported appear to have been read at the meetings, which must have been interesting ones. We believe no greater service can be rendered to the spread of a taste for natural science than an encouragement of these efforts at our public schools.

A NATURAL History Society has been organised in Baltimore, to be called the Maryland Academy of Sciences; its object being to promote scientific research, and to collect, preserve, and diffuse information relating to the sciences, especially those connected with the natural history of Maryland. Its first president is Philip T. Tyson; Vice-president, Dr. John G. Morris; Corresponding Secretary, Dr. Charles C. Bombaugh.

THE *Feuille des Jeunes Naturalistes* is a praiseworthy attempt by a small body of French naturalists to establish an international school journal of science and natural history for the boys of France, Germany, and England. Contributions, written in either of the three languages, are invited from any schoolboy; and they will be received from no other source. The proprietors are especially anxious to interest our English schools in their enterprise; and we gladly give publicity to a very novel and very admirable scheme. The subscription is four francs per annum. The editor is M. E. Dollfus, Dornach, Haut Rhin.

IN reference to Mr. Murphy's communication in our last number respecting the purplish pink colour of the sunlight, we learn from correspondents that it was noticed also at Tynemouth, at 5 P.M., on Sunday, the 22nd ult.; at Cambridge, at 10 A.M., on Monday, and in Gloucestershire on both these days. In all these cases the sky is described as being hasy at the time.

THE *American Gas-Light Journal* speaks of an invention which aims at the entire abolition of oils and all other lubricating material for boxes, slides, and every condition of motion where metallic friction is to be overcome or expected. It is claimed that such a result has been fully achieved, and there are engines now running with this material, which the proprietors aver have worked to complete satisfaction for weeks and months. It is the work of a scientific and practical gentleman, well known both in America and in Europe, who has spent a great many years in the study of physical forces and their effects, with especial reference to metals. The exact nature of the present invention cannot be given, for the reason that patents are being sought for in several countries in Europe, and any clear description of the materials and processes would be likely to defeat that end. It may, however, be said, in a general way, that the discovery—which has received the name of Metalline—consists of such combinations and manipulations of various metallic substances, as to make a surface on which the ordinary axles, cranks, pins, slides, &c., of iron, steel, brass, or any other metal, will run with much less friction, without heat that comes within the slightest possibility of danger, and without increase (in fact an actual decrease is claimed) of the motive power used. These, briefly, are the claims, and the inventor refers to a large number of trustworthy gentlemen who have examined and tried the thing, and speak from actual knowledge.

A MOVEMENT is being set on foot in Germany for an alteration in the laws regulating the sending of dangerous substances by rail. Hitherto ether, alcohol, phosphorus, &c., can only be sent by special trains plying but once a week between the principal stations. Dry guncotton is entirely excluded from the railways; manufacturers are in the habit of sending it moistened with a certain quantity of spirits of wine; it thereby loses its explosive properties and burns like ordinary cotton.

WE are glad to see "Cassell's Popular Educator" still devoting a large proportion of its space to science. In the June number articles occur devoted to the following natural sciences:—Ethnology, geology (illustrated with woodcuts, which we recognise as taken from well-known handbooks), botany (a continuation of a series of excellent elementary articles), mineralogy, meteorology, and the science of heat.

DR. C. H. SCHAIBLE, of the Royal Military Academy, Woolwich, sends us "The State and Education," an historical and critical essay, with special reference to Educational Reform. The subject is exhaustively treated under the heads—Historical Sketch of State education; Compulsory Instruction; State Instruction; Organisation of State Instruction in Germany; Voluntary Instruction; State Control of Instruction; and Reform of Education in England; and the general conclusion arrived at may be stated to be the necessity of general, compulsory, unsectarian, primary instruction for all children from six to fourteen years of age, under State control, and gratuitous for the poor.

AT a recent meeting of the French Horticultural Society, M. Duchartre gave a history of the investigations into the nature of the phenomenon of variegation. He considers it to be now completely established that variegation is of the nature of a contagious disease, which in the case of grafted plants can be communicated both from the stock to the graft and from the graft to the stock.

It has long been laid down as a maxim in botanical hand-books that variegation and double flowering never go together. Many botanists have, however recently doubted whether the law always holds good, and that the double phenomenon may sometimes occur appears now to be definitely established by an article contributed by Prof. Morren, of Liège, to the April and May number of the *Belgique Horticole*, in which he gives a description, accompanied by a drawing, of a wall-flower possessing both double flowers and variegated leaves. The plant has now been grown for several years by M. Em. Rodigas, of St. Trond.

M. Schutzenberger, Professor of Clinical Medicine at Strasburg, publishes an essay on higher instruction, in which he compares the system in vogue in France to those pursued in Germany, England, and America, and discusses the influence of the Napoleonic University system on the institutions for higher instruction.

Dr. R. Wolf, Professor at Zürich, reprints "The Discoveries of the Telescope, and their results in Astronomy," a lecture given at the public hall in Zürich.

From the same author we have a second part of a Manual of Mathematics, Physics, Geodesy, and Astronomy, copiously illustrated with woodcuts.

Professor Miquel, of the Hague, publishes the first part of a "Catalogus Musei botanici Lugduno-batavi," being a catalogue of the flora of Japan, with lists of the Japanese collections contained in the Leyden Herbarium.

The eighth vo'ume of Dr. Frisch's collected works of Kepler, containing the "Collectanea ex codicibus Pulkoviensibus," the "Judicium matris Kepleri," and some smaller treatises, lies on our table.

A Magazine is now published at Heidelberg under the title *Annalen der Oenologie* devoted, entirely to the discussion of the cultivation of the vine and the manufacture of wine. It is edited by Dr. Blankenhorn and Dr. Rösler.

Perhaps the most extraordinary instance of excessive and depraved appetite on record is that of a French soldier, named Tarare, whose case is described in vol. xxi. of the *Dictionnaire des Sciences Médicales*, by Dr. Percy. He was born near Lyons, and came up to Paris, where his first exploit was to eat a basket of apples—at a friend's expense. On various occasions he swallowed a series of corks and other indigestible materials, which produced such violent colic that he was obliged to attend the Hotel Dieu, and whilst being examined almost managed to swallow the watch-chain and seals of the surgeon in attendance, M. Giraud. Desault, on the occasion of one of these attacks of colic, tried to frighten him out of his gross habits by declaring that it would be necessary to open his stomach, and arranged the instruments; he ran away, and relieved himself by copious draughts of warm water. Soon after he found that his appetite had really increased to an excessive amount, pro› bly owing to the continued irritation produced by these absurd tricks. At 17 years of age, when only weighing 100lb., he could eat 24lb. of beef in as many hours. He now entered the army, and being recognised by the Surgeon-Major, M. Courville of the 9th Regiment of Hussars, he was detained for the sake of curiosity. From the day of his admission, he was ordered quadruple rations, with pickings and waste meat, but often slipped into the dispensary to finish off a poultice or two. One day he was observed to seize a large cat: and, after sucking its blood, left, in a very short time, only cleanly picked bones, the hair being rejected in the course of about half an hour, like other carnivora. He was fond of serpents and eels, swallowing them whole. On another occasion he consumed in a few minutes a repast, spread out for fifteen German workpeople, of milk, &c., after which he was blown out like a balloon. In the presence of some officers he swallowed, at one sitting, 30lb. of liver and lights. His insatiable appetite was for once in his life made useful, by his being selected to convey a correspondence between General Beauharnais and a French colonel, which was inserted in a box and swallowed; but he was caught and soundly thrashed. He fell under suspicion of having eaten a child fourteen months old. It is stated that he was of mild and gentle manners and aspect. After death his stomach was found in a very diseased condition.

The Tyneside Naturalists' Field Club is not only one of the most vigorous and truly scientific in the country, but is nearly the oldest, and probably one of the largest, numbering 600 members. At its 24th anniversary meeting recently held, the following gentlemen were elected as officers, viz.:—President—Mr. George S. Brady; Vice-Presidents—the Revs. W. Featherstonehaugh, B.A., J. F. Bigge, M.A., H. B. Tristram, LL.D., W. Greenwell, M.A., G. C. Abbs, M.A., A. M. Norman, M.A., J. C. Bruce, LL.D., A. Bethune, M.A., and R. F. Wheeler, M.A., Sir W. C. Trevelyan, Bart., Drs. Embleton and Charlton, and Messrs. R. B. Bowman, Richard Howse, George Hodge, Ralph Carr, R. Ingham, T. Sopwith, Rowland Burdon, George Wailes, and E. J. I. Browell. Treasurer—Mr. R. Y. Green. Local Secretaries—Durham, Mr. John Booth; Hexham, the Rev. W. T. Shields; Morpeth, Mr. W. Creighton. Committee—Messrs. Thomas Atthey, Jos. Blacklock, T. J. Bold, James Clepham, John Coppin, W. Dinning, D. O. Drewett, Albany Hancock, John Hancock, Jos. Watson, A. F. Marreco, and Dr. Philipson. Auditors—Messrs. J. S. Foster, and T. P. Barkas.

We have received from the Canadian Government Emigration Office a copy of the Year-Book of Canada for 1870, containing a vast mass of information respecting British North America, which will be very useful to those interested in the country. It also contains an interesting paper on the Climatology of British North America, written by Mr. G. T. Kingston, the director of the Magnetic Observatory at Toronto; an account of the Educational Establishments, by Mr. J. C. Patterson, of Ottawa; and a paper by Mr. T. Cross on Mining in Canada, both of which are of interest. One of the chief points in the latter paper is the statement that mining in Canada is every year assuming a more steady and settled character. The gold working in Nova Scotia has given less favourable results than in 1867, but the falling off is ascribed to the depth at which the lodes were being worked, and the inadequate nature of the machinery employed. The total yield in 1868 was 20,541 ounces; and the inspector expresses the opinion that gold mining in the province is yet far from that development which may be expected.

M. l'Abbe Vaullet, director of the hospital of Annecy, believes, says *Les Mondes*, that he has proved that the temperature of the department of Haute Savoie has gradually risen in a very appreciable manner during the last forty years. The mean temperature, formerly 8° to 9° C., now exceeds 10·5°. The proofs he adduces are the advance of the cultivation of the vine, and of grain, and the retreat of the glaciers. The causes of this amelioration of the climate M. Vaullet considers to be the disforesting, the destruction of hedge-rows, the clearing of uncultivated lands, the multiplication and maintenance of roads, the draining of marshes, and the increase of population and of cattle.

Dr. Thomas Andrews has recently delivered two lectures in the chemical lecture-room of Queen's College, Belfast—the first on carbon, the second on carbonic acid and carbonic oxide. They form a portion of a course of strictly scientific lectures, the attendance being confined entirely to working men, the admission by ticket, but without charge. On each occasion the hall was crowded.

ON THE PROGRESS OF BOTANY DURING 1869 *

I.

It had been my intention on the present occasion to have carried on the sketches of the general progress of biological science which I had attempted in 1862, 1864, 1866, and 1868; but I have, from various causes, being unable to bestow so much time as usual to the preparation of my address, and feel obliged to confine myself to a few points connected with subjects of special interest to myself, which, within the last two or three years, have made considerable advances.

The most striking are, without doubt, the results obtained from the recent explorations of the deep-sea faunas, and from the investigation of the tertiary deposits of the Arctic regions, which, although affecting two very different branches of natural science, I here couple together, as tending both of them to elucidate, in a remarkable degree, one of the most important among the disputed questions in biological history, the continuity of life through successive geological periods.

An excellent general sketch of the first discovery and progressive investigation of animal life at the bottom of the sea at great depths, up to the close of the season of 1868, is given by Dr. Carpenter in the Proceedings of the Royal Society, vol. xvii. No. 107, for December 17, 1868; the results of the still more important expedition of the past year have as yet been only generally stated by Mr. Gwyn Jeffreys, in the numbers of NATURE for Dec. 2 and 9, 1869; and by Dr. Carpenter in a lecture to the Royal Institution, published in the numbers of *Scientific Opinion* for March 23 and 30, and April 6 and 13 of the present year; and further details, as to the Madreporaria, are given by Dr. Duncan in the Proceedings of the Royal Society, 1 vol. xviii., No. 118, for March 24 of the present year; whilst, in North America, the chief conclusions to be drawn from those researches into the deep-sea fauna are clearly and concisely enumerated by Prof. Verrill, in the number of *Silliman's Journal* for January last, and some of the more detailed reports of the American explorations by Louis and Alexander Agassiz, and others, have been published in the Bulletin of the Museum of Comparative Zoology at Harvard College, Nos. 6, 7, and 9 to 13. For the knowledge of the data furnished by the Tertiary deposits of the Arctic regions we are indebted almost exclusively to the acute observations and able elucidations of Prof. O. Heer, in his "Flora Fossilis Arctica," in his paper on the fossil plants collected by Mr. Whymper in North Greenland, published in the last part of the Philosophical Transactions for 1869, and in the as yet only short general sketch of the results of the Swedish Spitzbergen expeditions, contained in the Genevan *Bibliothèque Universelle Archives Scientifiques* for December 1869.

It would be useless for me here to retrace, after Dr. Carpenter and Prof. Verrill, the outlines of the revolution which these marine discoveries have caused in the previously conceived theories, both as to the geographical distribution of marine animals, and the relative influences upon it of temperature and depth, and as to the actual temperature of the deep seas, or to enter into any details of the enormous additions thus made to our knowledge of the diversities of organic life; and it would be still further from my province to consider the geological conclusions to be drawn from them. My object is more especially to point out how these respective dips into the early history of marine animals and of terrestrial forests have afforded the strongest evidence we have yet obtained, that apparently unlimited permanency and total change can go on side by side without requiring for the latter any general catastrophe that should preclude the former.

There was a time, as we learn, when our chalk-cliffs, now high and dry, were being formed at the bottom of the sea, by the gradual growth and decay of Globigerinæ and the animals that fed on them; amongst others, for instance, *Rhizocrinus* and *Terebratulina Caput-serpentis*; and when the upheaval of the ground into an element where these animals could no longer live, arrested their progress in that direction, they had already spread over an area sufficiently extensive for some part of their race to maintain itself undisturbed, and so on from that time to the present day, by gradual dispersion or migration, in one direction or another, the same *Rhizocrinus* and *Terebratulina* have always been in possession of some genial locality, where they have continued from generation to generation, and still continue, with Globigerinæ and other animals, forming chalk at the bottom of the sea, unchanged in structural character, and rigidly conservative in habits and mode of life through the vast geological periods they have witnessed. So also there was a time when the hill sides of Greenland and Spitzbergen, now enveloped in never-melting ice and snows, were under a genial climate, clothed with forests, in which flourished *Taxodium distichum* (with *Sequoiæ*, *Magnoliæ*, and many others), and when these forests were destroyed by the general refrigeration, the Taxodium occupied an area extensive enough to include some districts in which it could still live and propagate; and whatever vicissitudes it may have met with in some parts, or even in the whole, of its original area, it has, by gradual extension and migration, always found some spot where it has gone on and thriven, and continued its race from generation to generation down to the present day, unchanged in character, and unmodified in its requirements. In both cases the permanent animals of the deep-sea bottom and the permanent trees of the terrestrial forests have witnessed a more or less partial or complete change in the races amongst which they were commingled. Some of these primitive associates, not endowed with the same means of dispersion, and confined to their original areas, were extinguished by the geological or climatological changes, and replaced by other races amongst which the permanent ones had penetrated, or by new immigrants from other areas; others again had spread like the permanent ones, but were less fitted for the new conditions in which they had become placed, and in the course of successive generations have been gradually modified by the Darwinian process of natural selection, the survivors of the fittest only among their descendants. If, in after times, the upheaved sea-bottom becomes again submerged, the frozen land becomes again suited for vegetation, they are again respectively covered with marine animals or vegetable life, derived from more or less adjacent regions, and more or less different from that which they originally supported, in proportion to the lapse of time and extent of physical changes which had intervened. Thus it is that we can perfectly agree with Dr. Duncan, that "this persistence (of type and species through ages, whilst their surroundings were changed over and over again) does not indicate that there have not been sufficient physical and biological changes during its lasting to alter the face of all things enough to give geologists the right of asserting the succession of several periods;" but we can, at the same time, feel that Dr Carpenter is in one sense justified in the proposition, that we may be said to be still living in the Cretaceous period. The chalk formation has been going on over some part of the North Atlantic sea-bed from its first commencement to the present day, in unbroken continuity and unchanged in character.

If once we admit as demonstrated the coexistence of indefinite permanency, and of gradual or rapid change of different races in the same area and under the same physical conditions, according to their constitutional idiosyncrasies, and also that one and the same race may be permanent, or more or less changing, according to local climatological or other physical conditions in which it may be placed, we have removed one of the great obstacles to the investigation of the history of races, the apparent want of uniformity in the laws which regulate the succession of forms. We may not only trace, with more confidence, such modifications of race through successive geological periods as Prof. Huxley has recently exhibited to us in respect of the horse, but we can understand more readily the absolute identity of certain species of plants inhabiting widely dissevered areas, of which the great majority of species are more or less different. One of the arguments brought forward against the community of origin of representative species in distant regions, such as temperate Europe and the Australian Alps, the Arctic Circle and Antarctic America, the Eastern United States and Japan respectively,—an argument which long appeared to me to have considerable weight,—was this:—that if disseverance and subsequent isolation results necessarily in a gradual modification by natural selection, how is it that when all are subjected to the same influences, the descendants of some races have become almost generically distinct in the two regions, whilst others are universally acknowledged as congeners, but specifically distinct, and others again are only slight varieties or have remained absolutely identical? To this we can now reply, with some confidence, that there is no more absolute uniformity in the results of natural selection than in any other of the phenomena of life. External influences act differently upon

* Address of G. Bentham, F.R.S., President of the Linnean Society, read at the Anniversary Meeting, May 24, 1870.

different constitutions. Were we to remove the whole flora and fauna of a country to a distant region, or, what comes to the same thing, change the external conditions of that flora and fauna, as to climate, physical influences, natural enemies, or other causes of destruction, means of protection, &c., we should now be taught to expect that some of the individual races would at once perish; others, more or less affected, might continue through several generations, but with decreasing vigour, and, in the course of years or ages, gradually die out, to be replaced by more vigorous neighbours or invaders; others again might see amongst their numerous and ever-varying offspring some few slightly modified, so as to be better suited for the new order of things; and experience has repeatedly shown that the change once begun may go on increasing through successive generations and a permanent representative species is formed, and some few races may find themselves quite as happy and vigorous under their new circumstances as under the old, and may go on as before, unchanged and unchanging.

Taking into consideration the new lights that have been thrown upon these subjects by the above investigations and by the numerous observations called forth by the development of the great Darwinian theories, amongst which I may include a few points adverted to in a paper on Cassia which I laid before you last year, it appears to me that in plants, at least, we may almost watch, as it were, the process of specific change actually going on, or at least we may observe different races now living in different stages of progress, from the slight local variation to the distinct species and genus. As a first step we may take, for instance, those races which are regarded by the majority of botanists as very variable species, such as *Rubus fruticosus*, *Rosa canina*, *Zornia diphylla*, *Cassia mimosoides*, &c.: we shall find in each some one form, which we call typical, generally prevalent over the greater part of the area of the race, whilst others more or less aberrant are more or less restricted to particular localities, the same varieties not occurring in disconnected stations with precisely the same combinations of character; and in the same proportions local and representative varieties and sub-species are being formed, but have not yet obtained sufficient advantages to prevent their being kept in check by their inter-communication (and probable cross-breeding) with their more robust type. The British rubologist or rhodologist transported to the south of France or to Hungary will still find one, or perhaps two or three, forms of bramble and dog-rose with which he is familiar; but if he wishes to discriminate the thirty or forty varieties or sub-species upon which he had spent so much labour and acuteness at home, he will find that he must recommence with a series of forms and combinations of characters quite new to him. The species is still the same; the varieties are changed. As examples of what we may call a second stage in the formation of species, we may adduce such plants as *Pelargonium australe* or *grossularoides* and *Nicotiana suaveolens* or *angustifolia*, to which I alluded in the above-mentioned paper on *Cassia*. Here we have one race, of no higher than specific grade in the ordinary acceptance of the term, inhabiting two countries which have long been widely dissevered (in the one case South Africa and Australia, in the other Chili and Australia), which, if originally introduced by accident from one country to the other, have been so at a time so remote as thoroughly to have acquired an indigenous character in both; in both are they widely spread and highly diversified, but amongst all their varieties one form only is identical in the two countries (*Pelargonium australe*, var. *erodiodes*, and *P. grossularioides*, var. *anceps; Nicotiana suaveolens*, var. *angustifolia*, and *N. angustifolia*, var. *acuminata*), and that so comparatively a rare one that it may be regarded as being in the course of extinction; whilst all other varieties, some of them very numerous in individuals over extended areas, and all connected by nice gradations, diverge nevertheless in the two countries in different directions and with different combinations of characters, no two of them growing in the two countries being at all connected but through the medium of that one which is still common to both. When that shall have expired the distinct species may be considered as established. A still further advance in specific change is exemplified in *Cassia* itself, in which I have shown that no less than eight or nine different modifications of type, sectional and sub-sectional, are common to South America, tropical Africa, and Australia, but without any specific or, at least, sub-specific identity, except perhaps in a few cases where a more modern interchange may be presumed. The original common specific types are extinct, the species have risen into sections. Common types of a still higher order have disappeared in the case of Proteaceæ, an order so perfectly natural and so clearly defined that we cannot refrain from speculating on the community of origin of the African and of the Australian races, both exceedingly numerous and reducible to definite groups—large and small well-marked genera in both countries, and yet not a single genus common to the two; not only the species, but the genera themselves, have become geographical. As in the varieties of *Pelargonium* and *Nicotiana*, so in that of the species of *Cassia* and of the genera of Proteaceæ, it is not to be denied that precisely similar modifications of character are observed in the two countries; but these modifications are differently combined, the changes in the organs are differently correlated. In Asiatico-African *Chamæcristes* a tendency to a particular change in the venation of the leaflet is accompanied by a certain change in the petiolar gland; in America the same change in the gland is correlated with a different alteration in the venation. In Australian Proteaceæ the glands of the torus are constantly deficient, with a certain inflorescence (cones with imbricate scales), which is always accompanied by them in Africa.

In selecting the above instances for illustration of what we may, without much strain upon the imagination, suppose to be cases of progressive change in races, it is not that they are isolated cases or exceptionally appropriate; for innumerable similar ones might be adduced. In the course of the detailed examination I have had successively to make of the floras of Europe, N.W. America, tropical America, tropical Africa, China, and Australia, I have everywhere observed that community of general type, in regions now dissevered, is, when once varied, accompanied by more or less of divergence in more special characters in different directions in the different countries.

G. BENTHAM

SURFACE-OCEANIC LIFE

IN the waiting-room at the Admiralty is a drawing 12 feet by 8 feet, which is attracting the attention of numerous scientific and naval men, who thoroughly appreciate the novel and complete manner in which the several groups of interesting marine life have been arranged, and the system and regularity upon which the arrangement has been carried out, and we may also add, for the benefit of the curious, that the beauty and colour of these grotesque forms would exceed the imagination of Gustave Doré. The work was entirely executed in H.M.S. *Rodney*, on her passage from China to England during the last six months, and extends over the China Sea, Indian and Atlantic Oceans. The subject of surface-oceanic life is particularly acceptable at the present time, as Dr. Carpenter, Mr. Gwyn Jeffreys, and Professor Wyville Thomson were last season engaged in examining the deep-sea life of the neighbouring ocean, and are likely to extend their investigations into the Bay of Biscay and Mediterranean Sea during the summer. These deep sea explorations should be energetically pursued, and we may earnestly hope that it will not be long before an honest rivalry is maintained in the Atlantic and European seas, and that other oceans and parts of the world may be dipped into by voyagers, for contributions to this useful branch of science.

Those who only know the sea under the aspect which it usually presents round our own coasts will hardly be acquainted with the fact that the surface of the ocean forms a world in itself, inhabited by myriads of strange and delicate creatures, as distinct in its conditions from the shore world as from the inhabitants of the dark mysterious depths whose oozy plain, shut off from the day by three miles' thickness of water, is tenanted by the lingering and stunted refugees of a world of animals now for the most part extinct. The creatures which inhabit the surface of the ocean are very many of them born and bred there; others, on the contrary, have left their parents at a very early age, being carried away from the shore by surface currents and drifted out to sea, there to pass through ever-changing forms, until the time comes for their return to shallower places and a life of grovelling on the ground. Although this picture contains more than six hundred drawings of marine animals, it does not represent much more than one-third of the actual labour incurred, duplicate and fac-simile drawings of all the creatures having been originally made. The author of this picture, Mr. Francis Ingram Palmer, has been employed surveying the coasts of Japan and China, and it was on his passage home that he devoted his attention to this subject.

SCIENTIFIC SERIALS

Max Schultze's Archiv für Mikroskop Anatomie, Band vi. Heft. 2, 1870, is a paper by M. J. C. Eberth on the termination of the Cutaneous Nerves. Eberth's experiments were undertaken upon the skin of man, of rabbits, guinea-pigs, dogs, and cats, but chiefly on that of man and of Albino rabbits; the processes of pigment cells in the other animals often closely resembling nerves when stained with gold chloride. The strength of the solution that was used varied from ½ to 1 per cent., in which portions of skin were allowed to soak for from ¼ to 4 hours. In the cutis of man the nerves form first a rich web of dark-edged fasciculi, which break up into a plexus of fine fibrils and small fasciculi of fibrils. These soon lose their medullary sheath, and enter more or less vertically into the papillæ in the form of fine axis cylinders with fusiform nuclei lying upon them. He particularly insists that the final finest terminations which can be followed to the attached surface of the epithelium are free and do not form a plexus. He corroborates the statements of Langerhans respecting the presence of peculiar cells in the deeper parts of the epidermis of stellate and fusiform shape; often with a distinct nucleus. They blacken with chloride of gold; but neither Eberth nor Langerhans have been able to trace their connection with nerves. These cells usually send off from five to eight simple or branched processes towards the surface, but only one or two towards the cutis.

IN the *Annales des Sciences Naturelles, Zoologie*, Paris, 1870, p. 1, is a contribution by M. Léon Vaillant to the anatomical investigation of the genus Pontobdella, the principal points of which we extract. M. Vaillant states that he has had peculiar opportunities of observing this genus of the Hirudinidæ, and the particular species he has investigated is that of the *P. verrucata*, so called on account of the proper zoonites or segments of the animal supporting four tubercles, though the *cutaneous* segments or zoonites only bear two. The total number of cutaneous zoonites is 67. The anterior orifice of the digestive system is placed at the centre of the anterior sucker. The posterior orifice opens dorsally just in front of the posterior sucker. The skin presents a dermis and an epidermis, the latter being composed of a delicate cuticle and of a layer of epithelial cells, corresponding to the pigmentary layer of Moquin Tandon. The dermis is composed of cells concealed by a network of what appear to be anastomosing tubes. Beneath the skin, and almost forming part of it, is a dense layer of smooth muscular tissue, the external fibres of which are circular, the deeper longitudinal. By the agency of these the locomotion of the animal is chiefly effected. Between the muscular layer and the digestive tube an immense number of yellow granules are found, which appear to be of the same nature as the unicellular glands described by Leydig, possessing fine ducts, that can in some instances be followed to the skin, and therefore almost precluding the idea of their being hepatic organs. The nervous system presents 22 ganglia, excluding the œsophageal collar; the last one is the largest, and is found in the anal sucker. No eyes have been discovered in them, and their relations to the outer world appear to be restricted to those derived from the sense of touch. The digestive organs present no remarkable deviations from that of the leeches in general. Its divisions are a proboscis, with its sheath; a crop; the gastro-ilial portion, and the rectum. The jaws are reduced to three minute projecting points. The crop extends quite to the posterior part of the body, and presents a series of constrictions. The gastro-ilial portion is a single tube lying above the *cul de sac*, formed posteriorly by the ingluvies, and appears to correspond to the true stomach of other animals. The circulation is effected through a closed system of vessels, and the contents of these vessels are colourless, and destitute of corpuscles. M. Vaillant considers that the blood is represented properly by the fluid contained in the general cavity of the body, which contains definite morphological elements. There are four principal vessels, a dorsal, ventral, and two lateral, and these lie in the muscular layers. The dorsal and ventral vessels communicate freely by large branches; the lateral vessels receive their blood from a delicate plexus of vessels distributed on the intestine, which, however, communicates with the dorso-ventral system; and it is probable that an oscillation of the fluid is constantly occurring from one set of vessels into the other. On the whole, the vascular system is much less complicated here than in the leech. The respiratory function is effected essentially if not exclusively by the skin, and there is no special organ for its performance. In regard to the secretions, reference has already been made to the unicellular glands of the skin; and the only others are some peri-œsophageal glands, which are generally considered to be salivary, and the muciparous follicles, which are ovoid vessels, six in number, on each side, placed in the testicular region, and opening externally with a ciliated orifice. The sexes are united in the same individual. The eggs are deposited either separately or several together enveloped in a common capsule.

IN the third part of M. Brown Séquard's "*Archives de Physiologie*" are the results of an investigation of the mode in which nerves terminate in smooth muscular tissue, by M. Hénocque. He has examined the smooth muscles of numerous vertebrate animals and of man, with a great variety of reagents, as serum, pyroligneous acid, chromic acid, and chloride of gold and potassium, which in a strength of one part in 200 he particularly recommends. He finds that the appearances presented are the same in all animals, and in all organs; and states that in following out the nerves towards their peripheral terminations, they may be found to form three plexuses or networks—namely, a fundamental plexus, with which numerous ganglia are associated, and which is situated *outside* the smooth muscle; an intermediate plexus; and lastly an intra-muscular plexus situated in the interior of the fasciculi of smooth fibres. The terminal fibres are everywhere identical, they divide dichotomously or anastomose, and end in a slight button or swelling, or in a punctiform manner. These little buttons are seated in various parts of the smooth muscular fibre, more frequently round the muscles or at the surface of the muscular fibres, or, finally, between them.

THE *American Naturalist* for May commences with an interesting article on the Indians of California, their manners and customs, by Edward E. Chever; followed by one on the "Time of the Mammoths," by Professor N. S. Shaler, in which he gives a full account of the geological distribution on the American continent of the different species of the genus *Elephas*. W. G. Binney contributes a paper on the "Mollusks of our Cellars."

IN the *Revue des Cours Scientifiques* for May 21 we have M. Faye's important paper on the form of Comets, which occupied one of the *Soirées Scientifiques de la Sorbonne*, and a continuation of M. Bernard's series on Suffocation by the Fumes of Charcoal. In the number for May 28 is an epitome of M. Belgrand's *résumé*, presented to the Academy of Sciences, of the prehistoric history of the Paris basin, to which we refer in another column; the Rectorial Address, by M. H. Kopp, to the University of Heidelberg, on the State of Science during the Middle Ages; and a paper by M. Bert on Physiology and Zoology.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 19.—A paper was read, entitled "On the Effects of Alcohol (*Ethyl Alcohol*) on the Human Body," by Dr. Parkes and Count Cyprian Wollowicz. The experiments given in detail by the authors were undertaken with a view of testing the physiological and especially the dietetic effects of alcohol, and to clear up some points left doubtful by previous observers. They were fortunate in obtaining as the subject of experiment a healthy and very intelligent soldier at twenty-eight, 5 feet 6 inches in height, weighing from 134lb. to 136lb., with a clean, smooth skin, a clear bright eye, good teeth, largely developed, powerful muscles, and but little fat. As he had been accustomed to smoke, he was allowed half an ounce of tobacco daily, lest the deprivation of it might disturb his health. The amount of alcohol administered varied, but it was never carried so far as to produce any extreme symptoms of narcotism.

The plan of observation was as follows:—For twenty-six days the man remained on a diet precisely similar as to food and times of meals in every respect, except that for the first eight days he took only water (in the shape of coffee, tea, and simple water); for the next six days he added to this diet rectified spirit, in such proportion that he took, in divided quantities, on the first day one fluid ounce (= 28 c. c.) of absolute alcohol; on the second day two fluid ounces; on the third day four ounces, and on the fifth and sixth days eight ounces on each day. He then returned to water for six days, and then for three days took on each day half a bottle (= 12 ounces, or 341 c. c.) of fine brandy, containing 48 per cent. of alcohol. Then for three days more he returned to water.

There were thus five periods, viz., of water-drinking, alcohol, water, brandy, water.

Before commencing the experiments, the man, who had been accustomed to take one or two pints of beer daily, abstained altogether from any alcoholic liquid for ten days.

During the first few days there was a gradual increase in weight, owing probably to the food being rather greater and the exercise less than before; equilibrium was reached on the eighth day, and the weight remained almost unchanged during the alcoholic period. There was slight decrease after alcohol; and on the last brandy day a slight increase, which was maintained in the after period. The general result appears to be that (other conditions remaining constant) the effect of alcohol in modifying weight is quite unimportant. The results of the experiments may best be given in relation to the different functions of the body; and first in regard to the temperature of the axilla and rectum, it appeared that when taken as above described, alcohol and brandy produced little change in the temperature of either the axilla or rectum; but what effect there was, was rather in the direction of increase than of diminution. Secondly, in regard to the circulation, it was found that the pulse was increased both in frequency and volume, rising in number from 77·5 before alcohol to a max. of 94·7 with the largest doses. The capillary circulation was increased, shown by flushing of face and neck, &c. As conclusions from the sphygmographic observations that were made, it followed that there was increased frequency of the ventricular contractions of the head, and increased rapidity of each contraction, the ventricle therefore doing more work in a given time, the period of the heart being much shortened, and the blood moving more freely through the capillaries, so that the increased quantity of blood which it is to be presumed was thrown into the arteries, was very quickly got rid of. Thirdly, in regard to its action on the renal secretions, the authors show there was a decided increase in the amount of water eliminated; but they demonstrate in opposition to previous experimenters that, as long as the ingress of nitrogen is the same, 8oz. of absolute alcohol and 12oz. of brandy have no effect, or only a trifling effect, on the processes which end in the elimination of nitrogen by the urine, and most decidedly do not lessen the elimination. Further, the influence of alcohol on the elimination of chlorine and phosphoric acid, and upon the free acidity of the urine, is inconsiderable. The action of alcohol on the elimination of nitrogen by the alvine discharges was probably inconsiderable, and no experiments were made upon its effects upon the pulmonary excretion.

Putting together the evidence derived from the pulse as felt by the finger, from the state of the cutaneous vessels, and from the sphygmographic tracings, it seems fair to conclude that the chief effects of alcohol on the circulation in health are on the ventricles (the rapidity with which contractions are accomplished being greatly increased), and on the capillaries (which are dilated and allow blood to pass more freely through them).

As regards the mode in which alcohol is eliminated from the body from the application of a colour test, they are of opinion that a good deal must be eliminated by the lungs, and still more by the skin. Some also, though only a small proportion, must be given off by the renal and alvine discharges.

They found that one or two fluid ounces of absolute alcohol, in divided doses, increased the appetite; 4oz. lessened it, and larger quantities almost entirely destroyed it.

Estimating the daily work of the heart at 122 tons lifted one foot, the heart during the alcoholic period did daily work in excess equal to lifting 15·8 tons one foot, and in the last two days did extra work to the amount of 24 tons lifted as far. After the alcohol was omitted, the heart showed signs of weakness.

From the general results of the experiments, it appears, that any quantity over 2oz. of absolute alcohol would certainly do harm to this man, and that as every function was performed perfectly without it, its use was wholly unnecessary. They concluded by remarking that they were hardly prepared, notwithstanding their previous experience, for the ease with which appetite may be destroyed, the heart unduly excited, and the capillary circulation improperly increased. Yet they recognise the great practical benefit that may be derived from the use of alcohol in rousing a failing appetite, exciting a feeble heart, and accelerating a languid capillary circulation, though, for these objects to be fulfilled satisfactorily, there is necessity for great moderation and caution.

Ethnological Society, May 24.—Anniversary meeting, Prof. Huxley, president, in the chair. The report of the council and the treasurer's report were read and adopted. These reports showed that the position of the society was highly satisfactory. The President delivered an address, in which he gave a history of the efforts which have been made for amalgamating the Ethnological and Anthropological Societies, and hinted at the desirableness of union being effected between several societies having kindred objects. He also referred to the encouragement which the British Association had, since the Nottingham meeting, given to ethnological science, by allowing the Biological section (D) to resolve itself into departments. The following is the result of the ballot for officers and council:—President, Prof. Huxley, LL.D., F.R.S. Vice-presidents: Dr. A. Campbell, Sir John Lubbock, Bart., M.P., F.R.S., E. B. Tylor, Thomas Wright. Honorary Treasurer: H. G. Bohn. Honorary General Secretary: Colonel A. Lane Fox. Honorary Foreign Secretary: Hyde Clarke. Council: W. Blackmore, Prof. Busk, F.R.S., G. Campbell, Dr. Barnard Davis, W. Boyd Dawkins, F.R.S., J. Dickinson, Robert Dunn, J. W. Flower, David Forbes, F.R.S., A. W. Franks, Rev. Canon Greenwell, A. Hamilton, F. Hindmarsh, T. McK. Hughes, Dr. Richard King, Sir R. I. Murchison, Bart., K.C.B., J. F. McLennan, Rev. Dr. Nicholas, E. B. Pusey.

Linnean Society, May 24.—Anniversary meeting. The officers and council for the year 1870-71 were elected as follows:—President, G. Bentham, F.R.S. Treasurer, W. Wilson Saunders, F.R.S. Secretaries: F. Currey, F.R.S., and H. T. Stainton, F.R.S. Members of the Council: Thos. Anderson, M.D., John Ball, F.R.S., J. J. Bennett, F.R.S., George Busk, F.R.S., M. Foster, M.D., A. Grote, J. D. Hooker, M.D., F.R.S., Henry Lee, Major Parry, R. C. A. Prior, M.D., T. Thomson, M.D., F.R.S.

Short obituary notices having been read of fourteen fellows and five foreign members who had died during the year, the President proceeded to deliver his annual address, of which a full report will be found in another column.

Geological Society, May 11.—Joseph Prestwich, president, in the chair. Sir William Bagge, Bart., M.P., Colonel James Leslie Tait, and Dr. C. C. Carwana, were elected Fellows of the Society.

"Notes on some specimens of Lower Silurian Trilobites." By E. Billings, F.G.S., Palæontologist of the Geological Survey of Canada.

The author first described a specimen of *Asaphus platycephalus*, in which the hypostome was not only preserved *in situ*, but also the remains (more or less well preserved) of eight pairs of legs, corresponding with the eight segments of the thorax, to the underside of which they had been attached. The appendages take their rise close to the central axis of each segment, and all curve forwards, and are thus most probably ambulatory rather than natatory feet. They appear to have had four or five articulations in each leg. Three small ovate tubercles on the pygidium may, perhaps, indicate the processes by which the respiratory feet were attached. Mr. Billings referred to the large number of Trilobites which have been examined, and expressed his belief that only the most perfectly preserved specimens are likely to have the organs on the underside preserved. Mr. Billings next described the doublure or pleura in the Trilobites, comparing it to that of *Limulus*. He then proceeded to describe a row of small scars and tubercles on the underside of the pleuræ, to which both Dr. Volborth and Dr. Eichwald believed soft swimming feet or hard horny legs had been attached. As these were first seen by Dr. Pander in a Russian Trilobite, Mr. Billings has called them "Panderian organs." He thinks, soft natatory appendages may have been attached to these scars. Mr. Billings directed attention to the *Protichnites* and *Climactichnites*, which he thinks may now be referred to *Crustacea*, belonging to the division *Trilobita*. Finally, he described a section of a rolled-up *Calymene senaria*, the interior cavity of which appears to be full of minute ovate bodies, from $\frac{1}{80}$ to $\frac{1}{100}$ of an inch in diameter. These small ovate bodies the author believes to be eggs.

"Note on the palpus and other appendages of *Asaphus*, from the Trenton Limestone, in the British Museum." By Henry Woodward, F.G.S., F.Z.S.

Mr. Woodward, when comparing the Trilobite sent over by Mr. Billings with specimens in the British Museum, presented by Dr. J. J. Bigsby, F.R.S., discovered upon the eroded upper surface of one of these, not only the hypostome exposed to view, but also three pairs of appendages, and what he believes to be the palpus of one of the maxillæ. This furnishes an additional fact to Mr. Billings's most interesting discovery, besides confirming its correctness. Mr. Woodward considers the so-called "Panderian organs" to be only the fulcral points upon which the pleuræ move, and showed that such structures exist in most recent Crustacea. He considered that the evidence tended to place the Trilobita near to, if not in, the Isopoda Normalia, and remarked that the prominence of the hypostome reminded one strongly of that organ in *Apus*, and suggested that we might fairly expect to find that the Trilobita presented a more generalised type of structure than their representatives at the present day, the modern Isopoda.

"On the Structure and Affinities of *Sigillaria*, *Calamites*, and *Calamodendron*." By J. W. Dawson, LL.D., F.R.S., F.G.S., Principal and Vice-Chancellor of M'Gill University, Montreal. The object of this paper was to illustrate the structure and affinities of the genera above named, more especially with reference to the author's previous papers on the "Structures in Coal," and the "Conditions of Accumulation of Coal," and to furnish new facts and conclusions as to the affinities of these plants. With reference to *Sigillaria*, a remarkably perfect specimen of the axis of a plant of this genus, from the coal-field of Nova Scotia, was described as having a transversely laminated pith of the *Sternbergia* type, a cylinder of woody tissue, scalariform internally, and reticulated or discigerous externally, the tissues much resembling those of Cycads. Medullary rays were apparent in this cylinder; and it was traversed by obliquely radiating bundles of scalariform vessels or fibres proceeding to the leaves. Other specimens were adduced to show that the species having this kind of axis had a thick outer bark of elongated or prosenchymatous cells. The author stated that Prof. Williamson had enabled him to examine stems found in the Lancashire coal-field, of the type of Binney's *Sigillaria vascularis*, which differed in some important points of structure from his specimens; and that another specimen, externally marked like *Sigillaria*, had been shown by Mr. Carruthers to be more akin to *Lepidodendron* in structure. These specimens, as well as the *Sigillaria elegans* illustrated by Brongniart, probably represented other types of Sigillarioid trees, and it is not improbable that the genus *Sigillaria*, as usually understood, really includes several distinct generic forms. The author had recognised six generic forms in a previous paper, and in his "Acadian Geology;" but the type described in the present paper was that which appeared to predominate in the fossil Sigillarian forests of Nova Scotia, and also in the mineral charcoal of the coal-beds. This was illustrated by descriptions of structures occurring in erect and prostrate *Sigillariæ*, on the surface of *Sternbergia*-casts, and in the coal itself. The erect Calamites of the coal formation of Nova Scotia illustrate in a remarkable manner the exterior surface of the stems of these plants, their foliage, their rhizomata, their roots, and their habit of growth. Their affinities were evidently with *Equisetaceæ*, as Brongniart and others had maintained, and as Carruthers and Schimper had recently illustrated. The internal structure of these plants, as shown by some specimens collected by Mr. Butterworth, of Manchester, and soon to be published by Prof. Williamson, showed that the stems were more advanced in structure than those of modern *Equiseta*, and enabled the author to explain the various appearances presented by these plants, when the external surface is preserved, wholly or in part, and when a cast of the internal cavity alone remains. It was further shown that the leaves of the ordinary Calamites are linear, angular, and transversely wrinkled, and different from those of the *Asterophyllites* properly so called, though some species, as *A. comosus*, Lindley, are leaves of Calamites. The *Calamodendra*, as described by Cotta, Binney, and others, and further illustrated by specimens from Nova Scotia, and by several interesting and undescribed forms in the collection of Prof. Williamson, are similar in general plan of structure to the Calamites, but much more woody plants; and, if allied to *Equisetaceæ*, are greatly more advanced in the structure of the stem than the modern representatives of that order. Specimens in the collection of Prof. Williamson show forms intermediate between Calamites and *Calamodendron*, so that possibly both may be included in one family; but much further information on this subject is required. The tissues of the higher *Calamodendra* are similar to those of Gymnospermous plants. The wood or vascular matter of the thin-walled Calamites consists of multiporous cells or vessels, in such species as have been examined. In conclusion, a table was exhibited showing the affinities of *Sigillariæ* on the one hand, through *Clathraria* and *Syringodendron* with *Lycopodiaceæ*; and on the other hand, through *Calamodendron* with *Equisetaceæ*; while in the other direction they presented links of connection with Cycads and Conifers.

"Notes on the Geology of Arisaig, Nova Scotia." By the Rev. D. Honeyman, D.C.L., F.G.S. The author referred to a previous paper on the Upper Silurian Rocks of Nova Scotia, which he stated appeared to him now to be generally repetitions of his Arisaig series. He noticed the occurrence of fossils in one of the beds previously supposed to be almost destitute of organic remains, and described the occurrence, in Arisaig township, of a band of crystalline rocks which appeared to contain *Eozoon*, and were probably of Laurentian age. A note from Prof. Rupert Jones, giving an account of the fossils referred to by Dr. Honeyman, was also read.

Chemical Society, May 19.—Warren De la Rue, F.R.S., vice-president, in the chair. Mr. S. H. Johnson was elected a fellow. Mr. Griffin exhibited and explained a new gas furnace which is capable of melting about three pounds of iron in little more than one hour.—Mr. Walenn described an advantageous method for coating cast-iron objects by electrolysis with copper or brass. The special peculiarity of the method consists in the circumstance that no hydrogen is evolved during the process. A calico printing valse and other articles, coated with brass, in this manner, were submitted to the inspection of the assembly.—Mr. Tookey, Assayer in the Japanese Imperial Mint, communicated a paper "On the Manipulations of Assays of Gold and Silver Bullion." The number of separate processes from the first weighing in of a piece of gold bullion to the second weighing out before its value can be ascertained are well known to all assayers. The author saves a good deal of time by proceeding in the following manner:—The bullions are placed in conical shaped platinum tubes, which, at their narrow ends, are closed with a perforated plate, and at the wider end are provided with a shoulder, so that they can be supported by a porcelain tile having circular holes. The tubes and holes are numbered. The entire arrangement is then immersed in hydric nitrate, &c.; in short, proceeded with as if a single bullion, instead of a batch of them had to be treated. With regard to the assay of silver bullion, the hammering and brushing of the buttons after they have been detached from the cupels, may be dispensed with by placing those buttons into the perforated cavities of a platinum plate, where they are fastened by a platinum wire, and immersing the plate in pure hydric chloride, which will dissolve all the bone ash adhering to the buttons. The cavities of the plate are numbered to correspond with the cupels in the muffle. —Mr. Perkin read a note "On some Bromine derivatives of Coumarin." The following definite compounds have been obtained by treating coumarin with bromine in different ways: dibromide of coumarin, $C_9 H O_2 Br_2$; bromo-coumarin, $C_9H_5 BrO_2$, and dibromo-coumarin, $C_9H_4Br_2O_2$. All the three compounds are easily soluble in hot alcohol, from which they crystallise out on cooling. Dibromide of coumarin fires at about 100°, bromo-coumarin at 110°, dibromo-coumarin at 174°. The two latter compounds form, when boiled with an aqueous solution of potassic hydrate, potassium salts of new acids, probably bromo, and dibromo-coumaric acids.—Dr. Divers made some remarks "On the precipitation of solutions of ammonic carbonate, sodic carbonate, and ammonic carbonate by calcic chloride." The results of these experiments are chiefly of interest as supplying a characteristic reaction for the carbonate. When ammonic carbonate is added in excess to an aqueous solution of ammonia and calcic chloride, the calcic carbonate is precipitated very slowly in the cold, whilst such precipitate is instantly produced when ammonic carbonate is added to a solution of caustic ammonia and calcic chloride in water.—Dr. Thudichum made a short communication about having obtained hydric acetate from fresh urine, which fact contradicts the statements of Berzelius, Lehmann, and Liebig.

EDINBURGH

Institution of Engineers, April 19.—Professor Macquorn Rankine, C.E., LL.D., president, in the chair.—"On the Patent Law." By Mr. R. S. Newall. After some general remarks Mr. Newall proceeded as follows:—In brief, then, my propositions are:—The appointment of a standing commission who shall examine, in public, all petitions and specifications, &c., before the granting of a patent. That when once a patent is granted, it shall be held as valid, if not assailed within two years, under certain conditions. I do not see why the inventor's letters patent should not be made as secure and held as sacred as the title-deeds of any kind of property. The commissioners to be selected by the Privy Council from among men who are intimately acquainted with the arts and the sciences. I would extend the term of the patent to twenty years, and make the cost payable in four periods of five years, charging 50*l.* for each. This also might tend to restrict the number of patents applied for. I would leave the granting of licenses entirely to the patentee. It may suit his convenience to carry on the manufacture of his invention himself, better than to grant licenses to others to oppose him; and if he has the monopoly conferred upon him, he ought to be allowed to make use of it as he thinks proper. You have no more right to demand that a monopolist should grant a license than I have to drive my cattle into my neighbour's field. It appears to me to be absolutely impossible to fix the price for royalty on the granting of a patent; that, of course, must altogether depend upon the value of the invention, which cannot possibly be ascertained until some years after the patent is granted. We might as well attempt to fix the price for ten years of any commodity sold by shopkeepers, or of land to be sold. I propose to grant patents for inventions, whether they are made by foreigners or British subjects. I would propose the infliction of imprisonment in the case of any one infringing a patent, and having previously been convicted of the same offence. If this remedy were adopted we should have fewer rogues to deal with in patent cases, and the inventor might have the enjoyment of his monopoly. Since I began my proposed amendment of the patent laws in 1848, I have had more dishonesty to contend with than I hope may ever fall to the lot of any patentee. I have had fourteen years' litigation in defending the patent for my invention "for laying down submarine cables" against infringement, by Glass and Elliot, the Telegraph Construction Company, and others. Instead of being rewarded for a most valuable invention, without which the Atlantic, Indian, and other cables could not have been laid down, I have had to spend years in attending to law, and the expenses have amounted to thousands of pounds, whilst the pirates have made large fortunes by means of my invention.

PHILADELPHIA

American Philosophical Society, April 15.—Prof. Cope exhibited the greater part of the skeleton of an extinct crocodilian from the Cretaceous Greensand of New Jersey, which represented a new species of the genus *Bottosomus*, which he called *B. tuberculatus*. It displayed marked characters of the genus not before ascertained. Dr. Hayden called attention to numerous points in the topography and geology of the Rocky Mountain region, exhibiting photographs in illustration of them.

May 6.—A paper by Prof. Alex. Winchell, of the University of Michigan, was read, entitled, "On the Geological Character and Equivalents of the Marshall Group in the United States."—An obituary notice of Horace Binney, jun., was read by Prof. C. J. Stille.—A description of some beads of complex construction found in an Indian grave on the Susquehanna River, in Pennsylvania, by Prof. S. S. Holdeman, was read by the Secretary. They were described as ovoid, apparently made from parts of four concentric cylinders of blue and white material, the blue ridged so as to give a striated appearance to the coloration.—Prof. Harrison Allen read a paper entitled, "Some effects of Age, as observed in the Osseous System," illustrated by changes in the forms of the pterygoid alæ, malar bone, &c.—Prof. Cope read a paper "On the Fishes of the Tertiary Shales of Green River, Wyoming territory," in which the fragment of the fauna described was indicated as presenting resemblances to that of Monte Bolca. Prof. Cope also exhibited the cranium of a Dicynodont reptile from the Cape Colony, which he regarded as new, and called it *Lystrosaurus frontosus*. The genus was near Ptychognathus, but differed in the horizontal shovel-like mandible received within the upper. The species was near the *Pt. latifrons* (Owen), but differed in the breadth of cranium exceeding the length, great interorbital width, prominent orbital tuberosities, very narrow front, &c. He exhibited specimens of more or less imperfect tusks from the Trias of Pennsylvania, which he referred to Dicynodont reptiles.—Prof. F. V. Hayden communicated an essay on the stratigraphy of certain tertiary rocks on the line of the Pacific Railroad, including, among others, a section of a remarkable anticlinal in the basin of Utah. The strata exhibited in this section embrace two hundred distinct layers, varying from two inches to four feet in thickness. At the eastern extremity they are vertical, at the western they are bent in the form of a bow. It is a remarkable illustration of an arch unaffected by heat that Dr. Hayden had seen in the West. Some of the layers were composed of fossil shells, among others, Unio, Paludina, Corbula, &c.; the species few, but the individuals numerous.

THE NATURAL HISTORY COLLECTIONS

WE have been favoured with a copy of a memorial, drawn up as long ago as 1858, by some of the most distinguished geologists and botanists in England, on the subject of the organisation of the British Museum Natural History Collections, the removal of which was then thought to be imminent. As our readers are aware, no steps towards this removal have yet been taken, but as the subject has been brought again before Parliament, it would be well that so carefully considered a document as this appears to be should be weighed in reference to any contemplated change in the governance and disposition of our national Natural History Collections.

It is further most desirable that gentlemen interested in this subject should communicate their views upon the proposals embodied in this memorial to the public, and such will be thankfully received by the Editor of NATURE. Of the nine memorialists, four are zoologists, all happily alive. Of the five botanists, on the other hand, Mr. Bentham alone survives; it is especially desirable that the opinions of botanists on so important a question should be heard.

Copy of a Memorial addressed to the Right Honourable the Chancellor of the Exchequer.

SIR,—The necessity of the removal of the Natural History departments from the British Museum having been recently brought prominently before the public, and it being understood that the question of their reorganisation in another locality is under consideration, the undersigned zoologists and botanists, professionally or otherwise engaged in the pursuit of natural science, feel it their duty to lay before Her Majesty's Government the views they entertain as to the arrangements by which national collections in Natural History can be best adapted to the two-fold object of the advancement of science, and its general diffusion among the public,—to show how far the Scientific Museums of the metropolis and its vicinity, in their present condition, answer these purposes, and to suggest such modifications or additional arrangements as appear requisite to render them more thoroughly efficient.

The Scientific Collections or Museums, whether Zoological or Botanical, required for the objects above stated, may be arranged under the following heads :—

1. A general and comprehensive Typical or Popular Museum, in which all prominent forms or types of Animals and Plants, recent or fossil, should be so displayed as to give the public an idea of the vast extent and variety of natural objects, to diffuse a general knowledge of the results obtained by science in their investigation and classification, and to serve as a general introduction to the student of Natural History.

2. A complete Scientific Museum, in which collections of all obtainable Animals and Plants and their parts, whether recent or fossil, and of a sufficient number of specimens, should be disposed conveniently for study; and to which should be exclusively attached an appropriate *library*, or collection of books and illustrations relating to science, wholly independent of any general library.

3. A comprehensive Economic Museum, in which Economic Products, whether Zoological or Botanical, with Illustrations of the processes by which they are obtained and applied to use, should be so disposed as best to assist the progress of Commerce and the Arts.

4. Collections of Living Animals and Plants, or Zoological and Botanical Gardens.

The Typical or Popular Museum, for the daily use of the general public, which might be advantageously annexed to the Scientific Museum, would require a large building, in a light, airy, and accessible situation. The collections should be displayed in spacious galleries, in glass cases, so closed as to protect them from the dirt and dust raised by the thousands who would visit them; and sufficient room should be allowed within the cases to admit of affixing to the specimens, without confusion, their names, and such illustrations as are necessary to render them intelligible and instructive to the student and the general public.

The Economic Museums and living Collections in Botany might be quite independent of the Zoological ones.

The Scientific Museum, in Zoology as in Botany, is the most important of all. It is indispensable for the study of natural science, although not suited for public exhibition. Without it the naturalist cannot even name or arrange the materials for the Typical, Economic or Living Collections, so as to convey any useful information to the public. The specimens, though in need of the same conditions of light, airiness, &c., as, and far more numerous than, those exposed in the Typical or Popular Museum, would occupy less space; and they would require a different arrangement, in order that the specimens might, without injury, be frequently taken from their receptacles for examination. This Scientific Museum, moreover, would be useless unless an appropriate library were included in the same building.

The union of the Zoological and Botanical Society Museums in one locality is of no importance. The juxtaposition of each with its corresponding Living Collection is desirable, but not necessary; although, in the case of Botany, an extensive Herbarium and Library are indispensable appendages to the Garden and Economic Museum.

The existing Natural History Collections accessible to men of science and to the public, in or near the metropolis, are the following :—

In Botany.—The Kew Herbarium, as a scientific collection, is the finest in the world, and its importance is universally acknowledged by botanists. It has an excellent scientific library attached to it; it is admirably situated; and being in proximity with, and under the immediate control of the head of, the botanic garden, it supersedes the necessity of a separate herbarium for the use of that garden and museum. But a great part of it is not the property of the State; there is no building permanently appropriated for its accommodation, and it does not include any collection of fossil plants.

The Botanical Collection of the British Museum, consisting chiefly of the Banksian Herbarium, is important, but very imperfect. It is badly situated, on account of the dust and dirt of Great Russell Street; and the want of space in the existing buildings of the British Museum would prevent its extension, even were there an adequate advantage in maintaining, at the cost of the State, two Herbaria or Scientific Botanic Museums so near together as those of London and Kew. The British Museum also contains a valuable collection of fossil plants, but not more readily available for science than its zoological collections.

There exists no typical or popular Botanical Museum for public inspection.

The efficiency of the Botanical Gardens and Museum of Economic Botany at Kew, as now organised, and the consequent advantages to science and the public, are too generally recognised to need any comment on the part of your memorialists.

In Zoology.—The British Museum contains a magnificent collection of recent and fossil animals, the property of the State, and intended both for public exhibition and for scientific use. But there is no room for its proper display, nor for the provision of the necessary accommodation for its study—still less for the separation of a *popular typical* series for public inspection, apart from the great mass of specimens whose importance is appreciated only by professed naturalists. And, in the attempt to combine the two, the public are only dazzled and confused by the multiplicity of unexplained objects, densely crowded together on the shelves and cases; the man of science is, for three days in the week, deprived of the opportunity of real study; and the specimens themselves suffer severely from the dust and dirt of the locality, increased manifold by the tread of the crowds who pass through the galleries on public days,—the necessity of access to the specimens on other days preventing their being arranged in hermetically closed cases.

A Museum of Economic Zoology has been commenced at South Kensington.

There is an unrivalled Zoological Garden or living collection, well situated in the Regent's Park, but not the property of the State, nor receiving any other than indirect assistance, in the terms on which its site is granted.

The measures which your memorialists would respectfully urge upon the consideration of Her Majesty's Government, with a view to rendering the collections really available for the purposes for which they are intended, are the following:—

That the Zoological Collections at present existing in the British Museum be separated into two distinct collections,—the one to form a Typical or Popular Museum, the other to constitute the basis of a complete Scientific Museum.

These Museums might be lodged in one and the same building, and be under one direction, provided they were arranged in such a manner as to be separately accessible; so that the one would always be open to the public, the other to the man of science, or any person seeking for special information. This arrangement would involve no more trouble, and would be as little expensive as any other which could answer its double purpose, as the Typical or Popular Museum might at once be made almost complete, and would require but very slight, if any, additions.

In fact, the plan proposed is only a further development of the system according to which the Entomological, Conchological, and Osteological collections in the British Museum are already worked.

That an appropriate Zoological Library be attached to its Scientific Museum, totally independent of the zoological portion of the Library of the British Museum, which, in the opinion of your memorialists, is inseparable from the general library.

That the Scientific Zoological Museum and Library be placed under one head, directly responsible to one of Her Majesty's Ministers, or under an organisation similar to that which is practically found so efficient in regard to Botany.

That the Museum of Economic Zoology at South Kensington be further developed.

Your memorialists recommend that the whole of the Kew Herbarium become the property of, and be maintained by, the State, as is now the case with a portion of it—that the Banksian Herbarium and the fossil plants be transferred to it from the British Museum—and that a permanent building be provided for the accommodation at Kew of the Scientific Museum of Botany so formed.*

This consolidation of the Herbaria of Kew with those of the British Museum would afford the means of including in the Botanical Scientific Museum a geographical botanical collection for the illustration of the colonial vegetation of the British Empire, which, considering the extreme importance of vegetable products to the commerce of this country, your memorialists are convinced would be felt to be a great advantage.

Your memorialists recommend further, that in place of the Banksian Herbarium and other miscellaneous botanical collections now in the British Museum and closed to the public, a Typical or Popular Museum of Botany be formed in the same building as that proposed for the Typical or Popular Museum of Zoology, and, like it, be open daily to the public.

Such a collection would require no great space; it would be inexpensive, besides being in the highest degree instructive; and, like the Typical or Popular Zoological Collection, it would be of the greatest value to the public, and to the teachers and students of the Metropolitan Colleges.

That the Botanical Scientific Museum and its Library, the Museum of Economic Botany, and the Botanic Garden, remain, as at present, under one head, directly responsible to one of Her Majesty's Ministers.

The undersigned memorialists, consisting wholly of Zoologists and Botanists, have offered no suggestions respecting the very valuable Mineralogical Collection in the British Museum, although aware that, in case it should be resolved that the Natural History Collections generally should be removed to another locality, the disposal of the minerals also will probably come under consideration.

GEORGE BENTHAM, V.P.L.S.

W. H. HARVEY, M.D., F.R.S. & Z.S., &c., Professor of Botany, University of Dublin.

THOMAS HUXLEY, F.R.S., Professor of Natural History, Government School of Mines, Jermyn Street.

Nov. 18, 1858

* Since this Memorial was written great changes have taken place in the extent and position of the Botanical collections both at Kew and the British Museum, and the above recommendations would require some modification. This applies especially to the fossil plants, which it seems highly desirable to retain within an easy distance of the principal geological collections, and which might be fully illustrated by including the geographical botanical collection in the typical museum in London.—[G. B., June 1870.]

LONGEVITY IN MAN AND ANIMALS

On Comparative Longevity in Man and the Lower Animals. By E. Ray Lankester, B.A., Junior Student of Christ Church, Oxford. (London: Macmillan and Co. 1870.)

IN this interesting little essay Mr. Lankester appears to have accumulated most of the facts with which we are at present acquainted, in respect to the duration of life. He defines longevity to be the length of time during which life is exhibited in an individual; but does not, of course, apply the term individual to entire masses proceeding, as in the case of *alsinastrum* and many polypes, from a process of asexual generation; and he proceeds to point out that there is a longevity belonging to the species, and a longevity characteristic of the individual, and further, that the average longevity of a species never equals its potential longevity, since a thousand accidents happen to destroy individuals at an early period of their lives; he then distinguishes between normal and absolute potential activity, and shows that in man alone do these two nearly coincide.

The two chief circumstances which favour longevity are high individualism, for this in itself requires time; and small expenditure, the latter embracing the wear and tear put forth in the procurement of food and in the reproduction of the species. In support of these statements Mr. Lankester then adduces a considerable number of the more trustworthy observations that have been made in reference to the longevity of individuals belonging to different classes of the animal kingdom, some of which we here append. Our knowledge, it appears from these tables, of the duration of life in the lower classes, is very imperfect. Amongst the Protozoa, *Spongilla fluviatilis* dies yearly, leaving gemmules. Amongst the Cœlenterata, *Hydra viridis* reproduces sexually in autumn and then dies. An *Actinia mesembryanthemum* has been living forty-two years in an aquarium and is still alive. Amongst the Crustacea, some of the larger crabs and lobsters must have attained a great age; but Mr. Lankester has observed one species, *Cheirocephalus diaphanus*, which developes from the egg, reproduces and dies in from two to three months. In the Insecta, the imago, as a rule, lives part of a year, from six months to a few hours, dying on reproduction. The length of life of the larva varies greatly in closely allied forms, from four years or more to a week. Fleas may live as long as nine months. Scarcely any observations have been made on the length of life in the molluscoidea and mollusca. Fish appear to have great tenacity of life. Thus, the carp is believed to have attained the age of 150 years, and the pike 267 years, if a ring with the following inscription is genuine—"I am the fish which was first of all put into this lake by the hands of the Governor of the Universe, Frederick II., the 5th of October, 1230." It weighed 350lbs., and was 19 feet long. Its skeleton was exhibited at Mannheim, and it was taken at Halibrun in Suabia in 1497. Of the Amphibia, the toad lives 36 years, the frog 12 to 16, and various tortoises are inferred to be of great age from their size. Amongst birds, the parrot, goose, falcon, and raven are long-lived, the two former reaching 100 to 120 years, and the two latter exceeding 150 years. Wrens only live two or three years. Amongst mammals, the whale and elephant have the longest term of life, both probably exceeding 100 years, and possibly reaching 200; horse 25, but occasionally reaching 40 years; ox 15 to 20 years; sheep and goat 12 years; lion 20 to 50 years; cat 9 to 18 years.

Mr. Lankester comments on these tolerably well ascertained facts, and shows how they support the theory that longevity depends on the influence of generative and personal expenditure.

The last part of the work is devoted to the longevity of man, satisfactory conclusions respecting whom are almost limited to the very highly civilised nations. Mr. Lankester appears to entertain no doubt that cases have occurred where the age of one hundred has been exceeded. We have limited ourselves to a brief epitome of the contents of Mr. Lankester's work, and cordially recommend it to our readers.

H. POWER

OUR BOOK SHELF

The Fuel of the Sun. By W. Matthieu Williams, F.C.S. (London: Simpkin, Marshall, and Co.)

WE have in the work before us a proof that a very interesting and readable volume may be produced, although the hypothesis which has called it into being may be one with which we do not agree. Mr. Williams discusses at great length the very perplexing question of the sun's fuel, nevertheless we do not think that his hypothesis is an improvement upon that of Helmholtz and Thomson. But let us hear the writer speak for himself. After having come to the conclusion that an atmosphere very similar to our own, but only more attenuated, pervades all space, he supposes that the sun, in its progress through space, encounters new portions of this atmosphere, and then asks the following question—"Does there exist in the actual arrangements of the solar system any machinery for stirring in an important quantity of the new atmospheric matter and ejecting the old? If so, the maintenance of the sun's heat may be fully accounted for." The question is answered in the affirmative; the atmosphere is supposed to be the sun's fuel, and the planetary attendants of the sun are supposed to perform the duty of stokers with untiring vigilance and efficiency. The mode of action of this atmospheric fuel in furnishing heat is supposed to be as follows:—"It is evident then that the first result of the great evolution of heat from mechanical condensation of the mixed atmosphere of aqueous vapour, carbonic acid, and free oxygen and nitrogen, will be the dissociation of the water and the carbonic acid. But there must somewhere be a height at which the temperature capable of effecting dissociation terminates; where the atmosphere of elementary gases fringes upon that of combined aqueous vapour, and where these separated gases must revert into reunion with a furious chemical energy which will be manifested by violent combustion. Thus we shall have a sphere of dissociated gases and a sphere of compound vapours separated by an interlying stratum of combining gases, a spherical shell of flame, constituting exactly what solar observers have described as the 'photosphere.'" In fine, Mr. Williams' hypothesis is "a perpetual bombardment of 165 millions of millions of tons of matter per second without in any degree altering the density, the bulk, or any other element of the solar constitution."

B. STEWART

Einleitung in die Physik. Bearbeitet von Professoren G. Karsten, F. Harms, und G. Weyer.

THE volume before us is introductory to the "Allgemeine Encyclopädie der Physik," which is in course of publication, under the general editorship of Professor Karsten. The authors endeavour to supply whatever would not naturally be found or expected in the separate treatises of which the Encyclopædia is made up, which have been written independently by specialist authors from their individual points of view. They add a systematic treatment of everything that may be considered auxiliary to the entire group of the physical sciences.

Professor Harms is the author of the most important part of the work—a philosophical and historical introduction to the whole subject. The discussion ranges over three principal heads—

1. What are the proper limits, and the true relations of physical science, and what distinctions can be drawn between it and the other sciences of matter?

2. What are the methods of physical inquiry, with a critical estimate of induction, of speculation or deduction, and of the theory of cognition (Erkenntniss-theorie) which has arisen in Germany since the days of Kant. This discussion is naturally conducted both historically and metaphysically. The rapid but exhaustive reviews of Bacon,

Locke, Hume, Sir J. Herschel, Mill, and Whewell—the only authors quoted on the subject of induction, will be specially interesting to English readers.

3. The philosophical basis of the conceptions at the root of the natural sciences, with a full treatment of Idealism and Materialism, and a discussion of the differences between matter passive and without force, and matter active, bound up, that is to say, with capacities of change of state.

Professor Karsten's contributions involve an enormous amount of statistical and bibliographical labour. Fifty pages are occupied with a complete catalogue of the literature of general physics. All the encyclopædias, all the scientific periodicals and collections, all the books on the history of science, and all the handbooks and general treatises of all modern nations, are gathered together in one most useful and naturally bewildering list. Germany, Switzerland, England, the United States, France, Belgium, Holland, Denmark, Sweden and Norway, Russia, Italy, Spain and Portugal, are the countries which contribute. The order in which we have given them exhibits the civilised world from the German professor's point of view.

A second treatise by the same author deals with all of what are called the universal properties of matter, and discusses in full the problems of chemical affinity and the newest theories of atoms. Little is really carried lower than the year 1860, but references are given to all books of importance published as late as 1867.

His third treatise gives us the methods of measurement, with full descriptions of the instruments and copious tables of comparison between the units of different countries. Professor G. Weyer finally supplies a separate work on the determinations of space and time. All questions of latitude and longitude, of apparent and real magnitude, are fully discussed, and the astronomical data which affect our estimates of time are exhibited in full.

We have preferred to give our readers a simple statement of what is contained in the closely-printed volume of 900 royal octavo pages before us. Detailed criticism of five separate treatises, in the space at our disposal, is a mere impossibility. It is sufficient to say here that every subject discussed is worked out in all the painstaking and exhaustive detail to which the separate volumes of Karsten's Encyclopädie previously published, have accustomed us. Such works are of the greatest possible service to literature. They are not produced in England. Our scientific men are too busy conquering new worlds, and lecturing on the exciting incidents of every fresh conquest. There is not a man too many thus engaged, but we confess that we sometimes turn with desire to our two great mediæval universities, where the liberality of our forefathers has established hundreds of fellowships, expressly that men might have leisure to devote themselves to lifelong studies. How is it that Oxford and Cambridge leave us to sigh for impossible translations of laborious books like this, which has been sent us principally by the University of Kiel?

W. J.

De l'abus des boissons alcooliques. Par L. F. E. Bergeret. (Paris: Baillière et fils.)

THE author, who is the senior physician of the Hospital D'Arbois (Jura), has for the last thirty years devoted special attention to the effects produced by the excessive use of alcoholic liquors. Though denying that alcohol is in any form a necessary of life, he fully admits that the moderate use of alcoholic liquors has its advantages, and the work has been written chiefly with the object of affording a popular illustration of their physiological action, and of exciting a wholesome fear of their abuse. The volume contains a large amount of very interesting information, and the results of much personal observation relating to the consequences of habitual intoxication.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

The Cretaceous Epoch

THE President of the Linnean Society having been good enough to credit me, in the interesting address which has just appeared in NATURE, with the doctrine that the formation of chalk has been going on continuously over some part of the North Atlantic sea-bed from the Cretaceous epoch to the present time, I feel it due to my friend and colleague, Prof. Wyville Thomson, to disclaim most explicitly the merit of having originated this doctrine, which entirely belongs to him. I regret that the form in which it was promulgated in my report of the *Lightning* expedition should have led to this misapprehension; but that form was adopted at my friend's express desire; and I have on every occasion (as in my recent lecture at the Royal Institution) spoken of the idea as exclusively *his*. Whilst myself fully accepting and advocating it, I am the more anxious that there should be no mistake in this matter, as it seems to me that the idea is one which must exert so important an influence on the future course of geological inquiry that its introduction will be one of the landmarks in the history of the science.

The *similarity* of the globigerina-mud, at present in process of formation, to the mesozoic chalk, had been recognised by various microscopists who had studied both—as Ehrenberg, Bailey, Williamson, Huxley, Wallich, and Sorby. But no one, so far as I am aware, had ventured to advocate the *unbroken continuity* of the chalk formation throughout the Tertiary and Quaternary periods, until it was pointed out by Prof. Wyville Thomson that there is no adequate evidence of its ever having ceased, though its locality has changed.

This doctrine has received most striking confirmation from the discovery of the persistence of numerous cretaceous types, more or less modified, not merely in our own explorations, but in those carried on by the United States Coast Survey in the Gulf of Mexico. That we could not expect to find the cretaceous fauna *as a whole* in our modern chalk is evident from the considerations so admirably set forth in Mr. Bentham's address; and if the cretaceous epoch is to be limited by the duration of that particular *ensemble*, it may, of course, be affirmed to have closed long since. But if there has been a continuous production of globigerina-mud from the time when the cretaceous area of Europe was a deep-sea-bed, the elevation of that sea-bed, so as to bring a large part of it above the surface, being probably coincident with the depression of what is now the North Atlantic Basin, to which the globigerinæ then migrated, and if there be found in the newly-formed chalk so large a number of representatives of the types most characteristic of the old, as indicates the continued prevalence of the same general, physical, and biological conditions, there is, I submit, a fair justification of the assertion (the pregnant words of which are Professor Wyville Thomson's) that "we may be said to be still living in the cretaceous epoch." And, as I ventured to put forth in the lecture referred to, the *onus probandi* now seems to me to rest on those who assert that this continuity has been interrupted, and that the chalk formation now in progress is anything else than a continuation of that of which Dover Cliff is composed.

Whilst "on my legs," I would venture to call the attention of geologists to the question which has been much considered by Professor Wyville Thomson and myself, whether we are not justified, by the probabilities of the case, in carrying *backwards* the continuity of the accumulation of Foraminiferal mud on the deep-sea bed, into geological epochs far more remote; since there must have been deep seas in all periods, and the changes which modified the climate and depth of the sea-bottom must have been for the most part sufficiently gradual to admit of the migration of animals to whose continued existence in the same locality those conditions were no longer favourable. It is a most interesting confirmation of the view we are disposed to entertain on this point, that, as I have recently learned from Sir William Logan, coccoliths and coccospheres have been discovered in some of the most ancient Palæozoic limestones of North America.

WILLIAM B. CARPENTER

[See also Prof. Gümbel's letter to Prof. Huxley on this subject in NATURE, vol. I. p. 657.—*Ed.*]

The Aye Aye

I FIRST saw the quotation from the *Pall Mall Gazette* in the columns of NATURE concerning the long finger nail of the Aye Aye, and the "exquisite argument" founded by Professor Owen upon it.

As a simple matter of fact, allow me to state that I kept a living Aye Aye (now preserved in the British Museum) in a large cage in the Mauritius, and as its food I gave it the maggot that infested branches of a species of Acacia. The animal used to spend its evenings in feeding, as follows. It listened attentively at the branches, tapping occasionally the most perforated parts; it then tore off pieces of the wood around the maggot hole, inserting the peculiar long finger as a probe from time to time, and ended by extracting the maggot by means of this long finger and its strong rodent teeth.

I have seen the operation scores of times.

Athenæum, May 28 HUMPHRY SANDWITH

Carp and Toads

IN the last number of NATURE you give an abstract of a paper by M. Duchemin on the destruction of carp by toads. The fact that carp are so destroyed is, or was, well known. Walton, in his "Complete Angler," says:—"And I have known of one (person) that has almost watched the pond, and at the fishing of the pond, found of seventy or eighty large carps not above five or six; and that he had foreborne longer to fish the said pond, but that he saw on a hot day in summer, a large carp swim near the top of the water with a frog upon his head; and that he, upon that occasion, caused his pond to be let dry; and I say, of seventy or eighty carps, only found five or six in the said pond, and those very sick and lean, and with every one a frog sticking so fast on the head of the said carps, that the frog would not be got off without extreme force or killing." Walton also mentions that pike are attacked and destroyed in the same manner. Walton wrote his "Complete Angler, or Contemplative Man's Recreation" in 1653. The confusion between frogs and toads was one likely to be made at a time when natural history was so little studied. In all other respects Walton's account agrees with M. Duchemin's. C. H. G.

Anticipated Destruction of the Cheesewring

I AM sure your readers will pardon me for drawing their attention to the very perilous situation of that remarkable pile of rocks, six or seven miles north of the town of Liskeard, in Cornwall, and known as the Wring-cheese or Cheesewring. Wilkie Collins, in his "Rambles beyond Railways," thus describes the general appearance of this natural curiosity:—"If a man dreamt of a great pile of stones in a nightmare, he would dream of such a pile as the Cheesewring. All the heaviest and largest of the seven thick slabs of which it is composed are at the top; all the lightest and smallest at the bottom. It rises perpendicularly to a height of thirty-two feet, without lateral support of any kind. The fifth and six rocks are of immense size and thickness, and overhang fearfully all round the four lower rocks which support them. All are perfectly irregular; the projections of one do not fit into the interstices of another; they are heaped up loosely in their extraordinary top-heavy form on slanting ground, half way down a steep hill." Of late years this hill has been so extensively quarried for granite that the workmen are now within a few paces of the Cheesewring itself. When a lease of the ground was first granted, it was stipulated that no stone should be removed within a certain distance of this well-known landmark, so as to prevent any possibility of its being destroyed. Now, however, the boundaries of the quarry have been so extended that powerful blasting operations are continually being carried on within a short distance of it, not without very great risk to the whole structure. In fact, it is on the eve of being destroyed, unless a vigorous and influential attempt is made to save it. Six months ago the Royal Institution of Cornwall sent a deputation of its members to report on the exact state of the Cheesewring; and although a memorial was addressed to the authorities of the Duchy of Cornwall, the owners of the property, praying that some means be adopted for the preservation of this extraordinary geological formation, no satisfactory reply has been hitherto received. Since, therefore, *local* influence appears to be of little or no avail, it is to be hoped that the matter will be taken up by those who are especially interested in the preservation of remarkable objects of this kind. The untimely fate of the great Tolmên last year should be remembered; and measures immediately adopted to avoid a repetition of a similar catastrophe within so short a period. Whatever is done should be begun speedily, or in the meantime the impending calamity may actually take place. E. H. W. DUNKIN

Greenwich

Left-handedness

I HAD been intending, if no one had anticipated me, to suggest what I have little doubt is the true explanation of the destruction of carp by toads. I see in p. 59 of NATURE for May 19, that Mr. Wade hints at this solution of the difficulty.

Let me take this opportunity of saying a word on Left-handedness. The late eminent anatomist, Professor Gratiolet, maintained that in the early stages of fœtal development, the anterior and middle lobes of the brain on the left side were in a more advanced condition than those on the right side, the balance being maintained by an opposite condition of the posterior lobes. Hence, in consequence of the well-known decussation of the nerve-roots, the right side of the body—so far as it is influenced by brain force—would, in early fœtal life, be better supplied with nervous power than the left side; and movements of the right arm would precede and be more perfect than those of the left. If Gratiolet's view is regarded as established (it has, I believe, been disputed), we have a physiological clue to the explanation of Right-handedness. In rare cases the development of the interior and middle lobes of the right side may precede that of the left; we shall then have Left-handedness.

May 21 M.A., CANT.

IN answer to Mr. Meyer's letter on this subject, I can only say that the question of the dependence of Left-handedness on abnormality of the subclavian artery cannot be settled by the authority of even so eminent an anatomist as Professor Hyrtl, when it is adduced against the facts I mentioned in my last note. That there have been cases like that quoted from Dr. Buchanan of transposition of viscera and left-handedness occurring in the same individual, and that they will be observed again, I do not doubt. Otherwise the conclusion would be that such abnormalities prevent left-handedness, which no one pretends. What I venture to think the cases already on record prove is, that the one condition has no relation to the other in either causing or preventing it.

With regard to the origin of the right subclavian direct from the end of the transverse aorta, though I have met with several cases of this variation, they were in subjects whose history was unknown; while, unlike complete transposition of the viscera, the condition cannot of course be recognised during life. But at the last meeting of the Pathological Society, a case of aneurism with this abnormality was brought forward; and, by the kindness of Dr. Peacock, who exhibited it, I am informed that the patient was undoubtedly right-handed during life.

Even apart from facts like this, one would scarcely expect to find the explanation of left-handedness in abnormalities affecting only the upper extremity. The condition is one of the eye, the leg, and the whole body. This one discovers in using the microscope, shooting, and batting; and the facts of aphasia appear to show that we are all, to use M. Broca's phrase, *gauchers de cerveau*. In fact, we must first explain normal right-handedness, and that not only as seen in man, but also in the paces of the horse, and in many other alternate or otherwise unsymmetrical movements of animals.

The only anatomical explanation of right-handedness I have met with is the unconfirmed statement of Gratiolet that the left half of the brain is developed more rapidly than the right. But even if true, this would only throw back the question to the origin of such a condition of the brain.

That the primitive habit of bilaterally symmetrical animals is to use right and left organs equally, seems probable, and also that when more complicated movements have to be performed, one limb alone must be chosen and so in time become more skilful. This preference may be transmitted hereditarily. But, granting in addition that the convenience of the community requires that all its members should select the same limb, it yet is not clear by what process of natural selection the right one has come to be universally preferred to the left—how, in fact, except from practice, right-handedness has come to be dexterity, and left-handedness *gaucherie*.

This question of the reason of symmetrical organs having different functions might perhaps be elucidated by a study of the conditions under which deviation from bilateral symmetry occurs in the *structures* of animal life, even among the highest arthropods and vertebrates. P. S.

May 23

The "Chromatic Octave"

RENEWED attention to the "chromatic octave" tempts me to suggest an experiment. There used to be a gentleman, Smith, I believe, by name, who refuted the undulatory theory by means of a disc, divided into black and white sections, which he whirled with very high velocities, producing colours (so the *Times* positively stated) varying according to the velocities. It is plain that such a result might on the contrary confirm the theory, if, for instance, the disc were divided into 400 black and 400 white sectors, and whirled at the rate of one or two million million times a second. It is also plain that Mr. Smith, in the words of an authority who has been quoted in your columns for weightier judgments, would have blown his disc into smoke first. But *once* a second is only 40 octaves below a million million times; and it is just possible that something practicable between the two might throw light on the "chromatic octave," among other things. There are some obvious objections: the question is, whether they make it worth while to repeat Mr. Smith's experiments.

I have just received the number of *Poggendorff* (Oct. 1867, CXXXI.) containing Professor Listing's paper (p. 564), referred to by Mr. Barrett in NATURE for Jan. 13 and March 31. I did not expect it would support Mr. Barrett, but I was surprised to find how directly it contradicts him. "Listing," he says, "concludes that, although physiologically and psychologically there may be differences, yet there is an indisputable *physical* basis for the analogy between tones and colours." I had myself, at the end of my remarks in NATURE for Feb. 3, admitted the "physical basis" in that sense "of the word *physical* which excludes biological relations," and the remark is too trivial to have formed Listing's *conclusion*. It forms part of a sentence in the first page of the paper. "The analogy between tones and colours, which has often been pursued with excessive predilection, and which certainly has an indisputable physical basis, has against it numerous points of disagreement (*Discongruenzen*), even now not in general sufficiently attended to, which depend rather on the physiological and psychological aspect of the phenomena." In the same page of the number it clearly appears how much is meant by the *physical basis*. "Physically," he says, "it is the period of vibration that determines both tone and colour; but the physiological effects stand in very different relations to the common element in the two cases." He proceeds to show, as correctly explained by Mr. Barrett, that the several colours divide the spectrum in an arithmetical progression of their rapidities of vibration; and at the end of the paper, contrasting this phenomenon with the geometrical progression of a uniform series of tones, he says: "This point of disagreement, a very vital one in my opinion, between the scales of tone and colour, may be briefly stated thus: *In the musical scale* (chromatic and with equal temperament*) *the logarithms of the tones are in arithmetical progression, in the scale of colour the colours themselves.*" That this should mean what Mr. Barrett understands it to mean, you must read *agreement* for *disagreement.*

Of the reality of Listing's result, I suppose there can hardly be any doubt; and I am glad that Mr. Barrett has corrected my suggestion that it probably represented a conventional demarcation. There does seem something arbitrary in the number of divisions made, but their positions represent a mean among the impressions of different observers as to the boundaries between colours answering to the names assigned; and the accuracy of these determinations may be fairly estimated by likening them to the case of a person who, having to divide a space of nine inches into nine equal parts, should be correct *as often as not* within one 24th of an inch. But the most important point is this, that the observers would not be aided, but must rather have been distracted, by the spaces actually occupied by the colours in the spectrum. For the observations were made on two different spectra, the irregular one obtained from the prism, and the diffraction spectrum in which the colours proceed uniformly by wave-lengths; and the result was a division into equal spaces, not on either of these visible spectra, but on the ideal spectrum, which should proceed uniformly by rapidities of vibration. It would have been in the spirit of good German precedents if we had been given some measure of the variation between different observers.

It must be confessed that all this is damaging to the theory of a "chromatic octave," essentially a theory of geometrical progression. Still more obviously damaging is the fact that "lavender" would be the octave above something so unlike it as "brown," or "brown" and "red."

Mr. Murphy's argument (NATURE, April 28) seems to assume that complementary wave-lengths must be in *some* constant ratio. His theory is, at any rate, inconsistent with his author's; for primary red and blue would be nearly complementary, so that "true white" could not be produced by any mere preponderance of blue, and would be white only to the green-blind.

C. J. MONRO

* If this is what is meant by "chromatischen gleichschwebenden."

IN Mr. Murphy's interesting letter in No. 26 of NATURE, April 28, 1870, he assumes that the number expressing the frequency of vibration producing a colour complementary to another, is the geometrical mean between the frequency of vibrations corresponding to that other, and its double. By this means he does not get colours complementary from sunlight. Thus red and bluish green (whose numbers are respectively 36·4, 48·3) are not complementary on his hypothesis; which would require the number for bluish green to be 51·47. So for yellow and indigo, the numbers are 41·4, 54·7, but should be 41·4, 58·4. This he attributes to the impurity of the solar spectrum. There seems as much reason, however, for taking the *harmonic mean* instead of the geometric; and, on this supposition (the harmonic mean between two quantities being twice their product divided by their sum), the numbers would be red, 36·4; bluish-green, 48·5; yellow, 41·4; indigo, 55·2. The second and fourth, 48·5, 55·2, are not very different from 48·3, 54·7. Taking then a colour twice over in the spectrum and its intermediate complementary, the relation between the three would be that of a musical note, its fifth and its octave.

Little Wratting, Suffolk, May 16 M.A.

The Colour of the Moon by Day and by Night

CAN any of your readers give me a full explanation of the reason why the moon looks white by day and yellow by night? The light that proceeds from it is of course the same at both periods; whence does the change in appearance arise? Two reasons occur at first thought, but they do not completely satisfy the many requirements of the problem. The one is, that the light, being really somewhat yellow, though less so than it often appears to be, passes in daytime through an atmosphere made blue by the solar rays, and the blue and yellow neutralising each other, the moon looks white. The other reason is, that as the evening closes in, the twilight becomes purple, and the moon being but moderately yellow in itself, looks more intensely yellow by contrast. All this is correct so far as it goes; but I do not see why the moon should often look extremely yellow in the middle of the night after twilight has quite disappeared. Does it show that the light, one knows not exactly whence it comes, which is found even on clouded and moonless nights, is purple? There are some grounds for this hypothesis, because the moon almost always, as I have been assured by a practical astronomer, looks comparatively white through a telescope, which of course isolates the field of vision. Also, it seems to me that the street gaslights are just as yellow at midnight as in twilight; the stars, also, commonly look yellow all the night through. It is strange that the very frequent and beautiful phenomenon of the white moon of the day suddenly turning yellow as the evening closes in, should not have long since attracted scientific comment.

F. G.

What is a Boulder?

A CORRESPONDENT in your journal of the 26th of May inquires about the size of boulders, and states that he cannot find any definition of the word which gives a notion of its size accurate enough for scientific purposes.

There are several definitions of boulder-stones given by geologists and others, which determine their size within tolerably narrow limits.

Dr. Page defines boulders as being "any rounded or water-worn *blocks* of stone, which would not, from their size, be regarded as pebbles or gravel;" or generally, "any *large* water-worn and smoothed blocks, found embedded in the clays and gravels of the drift formation." The maximum size he assigns to gravel is the size of a hen's egg, and pebbles may be ten times as large as this, so that the smallest boulder may be regarded as being of more than a foot diameter. Again, the same author describes boulders as being "often of great size, and weighing many tons."

Dr. Nuttall, in his Pronouncing Dictionary, defines boulders as being "large round pebbles;" and it would not often be possible to put even a small pebble in one's waistcoat pocket, and it must be a high wind that could blow a large pebble for any distance.

Chambers gives, as the etymology of boulder, or bowlder, as it is sometimes spelt, the verb "to bowl," and so states that it means a rolling stone, and, afterwards, one rounded by water. Now boulders are very often found separate, and at some distance from each other, and how could they have been rounded separately, without friction with each other, if they had been otherwise than large?

These arguments may be enough to show that boulders cannot be very small, and, in fact, may vary from stones 18 inches diameter, or thereabouts, to immense rocks of 10 feet diameter, "weighing many tons."

Christ's Hospital, May 27 J. W. CRAWLEY

Scandinavian Skulls

MR. G. STRACHEY, commenting in your columns on a recent lecture of Professor Huxley's, makes the following statements:—

"According to the highest Copenhagen authorities, there is no ground whatever for the assertion that modern Scandinavian skulls are of the long type. It is equally incorrect to say that Scandinavians are fair-haired and blue-eyed."

Without at all wishing to endorse Prof. Huxley's views on British ethnology, which I regard as rather bold than sound, I may be allowed to express my astonishment at the statements just quoted.

The skull measurements of Retzius, Van der Hoeven, and Barnard Davis all exhibit the Swedes as a more or less dolichokephalous people. My own measurements of the living head (Anthrop. Memoirs, ii. 351, and iii. 378) tend to controvert both Mr. Strachey's facts and Prof. Huxley's theory. Lastly, I should be glad to know where in the world fair hair and blue (or light) eyes are to be found, if not in Scandinavia. They are not universal there, nor any where else, but I do not think they are anywhere more common, except possibly in Lithuania or Esthonia.

Clifton, June 7 JOHN BEDDOE

Formation of Caverns

IN NATURE of 21st April, Mr. W. Boyd Dawkins, writing of caves in Yorkshire, tells us:—"All have been at one time or other subterranean water-courses." In the *Popular Science Review* for October 1869, the same gentleman writes:—"The ceiling, at the time of its deposition, must have been supported by a layer of cave earth." With your permission I will explain the character of a phenomenon, which I have published in my "New Pages of Natural History" (Newby, 1868), which may suggest to Mr. Dawkins the manner in which the caves at Streddle and Kent's Hole were formed. In the province of Poona, Bombay, the Ghar Nuddee (white river) has, in the mountains near its source, several lime formations spanning its level. In the dry season the river runs below as a subterranean stream; in the Monsoon it runs over this sheet of lime, which varies in thickness from a few inches to two feet along the centre or crown of the cavity, increasing in thickness towards the sides; there are several fissures on the surface; the hole at the upper end is smaller than that at the lower; the whole formation is in layers, and is due to water containing vast quantities of lime in solution. Originally there was a dip or hollow place on the spot, which gradually filled with all sorts of materials, till they grew nearly to the level of the dry season stream. In this condition the first thin sheet of lime was deposited on them, till by successive seasons the formation grew into a substantial covering composed of yearly layers. As there were perishable materials down below, they subsided, so that the lime covering, having in places no support, gave way to the force of the water, or to the weight of boulders hurled upon it, and water found admission between the lime sheet and the buried materials; as these were more moveable than the covering, they gradually washed out, and left the river to resume its ancient course beneath a covering of its own formation. Of course subterranean streams may excavate caverns; but if these streams owe their origin to percolation only, no large organic remains will be found in the caverns. If these are formed after the fashion of the Ghara caves, some organic remains may still be found, though waters have washed through them for years. When these lime formations withstand all the forces to which they are subjected, and have grown into large hills, the materials which formed the mould of the cave are still *in situ*, the perishable portions have changed into an oily, loamy soil; but bones, pebbles, and other materials are there mixed up with the stalagmite, which originally forming upon the surface of these materials, sunk and broke up as the supports failed, and remain, as Mr. Dawkins found them in Kent's Hole. H. P. MALET

The Anglo-Saxon Conquest

I SAW, with perfect clearness, the grounds upon which Prof. Rolleston now rests his defence. It is assumed that we can identify, to a nicety, the precise period of an interment, having no recording date, that took place fourteen or fifteen hundred years ago. I need not contest or discuss this point, but I am at liberty to doubt it.

The Britons petitioned Rome for assistance in A.D. 446. Cerdic landed in 494; the *groans of the Britons* were a piteous wail of "old men and children." The interval, taking it at three generations, passed in constant warfare, would not restore the balance of youth removed by conscription prior to A.D. 418, which circumstance therefore remains in part as an element to affect the general average of assumed longevity in the time of Cerdic. I urge this, with all respect, not as affecting, in any way, the real facts discovered or expounded by Prof. Rolleston, with whose address I was very much gratified; but only as affecting certain conclusions sought to be founded thereon. A. HALL

Curious Effect of the Words "Carmine" and "Germinal Matter"

DURING the twelve or thirteen years that Mr. Huxley has performed the duties of Examiner at the University of London, it appears that he has been much disturbed by the frequent use the candidates have made of the words, "cell," "germinal matter," and "carmine." He says: "*I declare to you I believe it will take me two years at least of absolute rest from the business of an examiner to hear either of the words without a sort of inward shudder.*" * This is surely a very remarkable declaration on the part of the examiner, since it is extremely doubtful if hearing these words ever made anyone else shudder, and if any other words written or spoken ever produced an effect so exceptional upon Mr. Huxley. LIONEL BEALE

Holly Berries

WILL some learned botanist, or Darwinian theorist, kindly inform me through the columns of NATURE why some holly berries appear obnoxious to birds? This is a great holly neighbourhood, and there are at present several trees actually loaded with ripe berries; the ground is also thickly strewed with berries beneath the trees, and yet not a single species of bird appears to eat them. Last winter the holly trees bore an abundance of berries, but the majority of the trees were stripped by the migratory *Turdi*, &c., as early as the beginning of February. I presume, in the "struggle for existence" these berries, obnoxious to birds, will stand a better chance of propagating and increasing that peculiar variety, and in course of time raise a distinct and well marked species.

Thruxton, May 23 HENRY REEKS

Origin of Languages

IT seems to me that your correspondents, Mr. Taylor and S. J., have discovered merely imaginary differences between the origin of species and the origin of languages. Mr. Taylor sees an essential difference in the fact that in the one case the process "is carried on by the countless efforts of *rational* beings," whilst in the other case there is "*reasonless* variation and selection."

* Address on Medical Education," *Lancet*, June 4th, 1870.

But I think the analogy still holds good, inasmuch as the "gradual variation, &c., of a few primary sounds," is not the result of an *intention* to originate a new language, any more than the origination of a new species of animal by natural selection is *intentional* on the part of the animals engaged in the struggle for life.

S. J.'s "impression is that the dialects which run wild are much more variable than those under man's care, which is the reverse of the case with wild and domestic animals and plants." But it must be remembered that it is the object of the "host of schoolmasters, lexicons, and grammars," who "watch over the Queen's English" to make that language uniform, to check its variations. If breeders of cattle made an effort to obtain perfect uniformity in a certain species of animal, I have no doubt that the wild herds of that animal, if allowed to exist under different conditions, would show much more variation "than those under man's care." But I question whether, in spite of the conservative influences of "schoolmasters, lexicons, and grammars" languages do not undergo as much variation through the *artificial selection* of writers, whose aim it is to make language more and more expressive, as animals and plants undergo through the artificial selection of breeders and agriculturists.

King's Lynn, May 28 ARTHUR RANSOM

STONE IMPLEMENTS FROM BURMA

SOME notes on the stone implements of Burma, by W. Theobald, jun., of the Geological Survey of India, contained in the number of the Proceedings of the Asiatic Society of Bengal for July, 1869, seem worthy of notice in these pages. "The implements are curious as differing in form and type, not only from anything found in India, but from anything hitherto described from any part of Europe, though any implement yet found in India has its precise analogue in Europe." According to Mr. Theobald, not only is the form but the material remarkable, as these Burmese implements are fashioned either of basalt or some schistose rock, quite unlike anything to be met with in the district where the implements themselves occur; a fact which he thinks points to their having been brought down from Upper Burma (where such implements are common) by the original settlers of the country.

That curious superstition which prevails over almost the whole of the globe, and connects the origin of these stone implements with the "thunderbolt," is found also in Burma. They are there called *mo-gio*, or thunderbolts, and are believed to accompany the lightning. If a flash of lightning is seen to strike the ground, and an earthen vessel is inverted over the spot, in the course of a year or so the *mo-gio* will be found in it, having worked its way back again to the surface by its own recoil.

The classical, or rather Plinian, view of this subject has been well given by Bishop Marbodæus, who wrote his Book "De Gemmis" early in the 12th century, and who thus speaks of the Ceraunius:—

> Ventorum rabie cum turbidus æstuat aër,
> Cum tonat horrendum, cum fulgurat igneus æther,
> Nubibus elisus cælo cadit ille lapillus,
> Cujus apud Græcos extat de fulmine nomen.

Its virtues were great in Europe as preserving from injury by lightning or shipwreck, and they had even aggressive as well as prophylactic powers, enabling the possessors to take beleaguered cities and to destroy hostile fleets.

In Burma they are also highly valued, but are put to crucial tests to prove them to be the genuine article, before a purchaser pins his faith to them. One test is that if wrapped in cloth and fired at with a gun, no effect will be produced either on the cloth or its contents, however near the aim may be taken, and it is from its presence producing invulnerability in its wearer that the *mo-gio* is mainly valued. It may be observed that it is not stated whether it is the seller who is entrusted to take aim with the gun. Another test of its celestial origin is placing it on a mat with a quantity of rice. If genuine, no fowl or other creature will venture near it. Again, a plaintain tree cut down with it ought to die, and not, as is usual, to send up a new shoot. If genuine, it preserves from fire, but it has also great medicinal virtues, and a small chip administered internally is considered a cure for inflammation of the liver or other internal organs, and is also a specific for ophthalmia. The virtues of stone axes in Germany, as summarised by Preusker in his "Blicke in die vaterländische Vorzeit," are curiously similar to those of the Burmese *mo-gios*. They preserve the house in which they are from lightning, they perspire when a storm is approaching, they are good for diseases of man and beast, they increase the milk of cows, they assist the birth of children, and powder scraped from them may be taken with advantage internally as a remedy for certain diseases.

The types of these Burmese instruments described by Mr. Theobald seem susceptible of arrangement under four heads.

1. "A rough, stout, wedge-shaped instrument," which, to judge from the figure, resembles closely the better finished specimens of flint hatchets, of the type which occurs in the Danish Kjökkenmöddings.

This form is very rare.

2. A hatchet with flat sides converging towards the base, which is square, and with a segmental edge, much like a common German form.

This type is common.

3. A long adze, with square, slightly converging sides, and a bevelled segmental edge, in character much resembling some of the implements discovered in Java, Borneo, and Sumatra, and also a New Zealand form; and—

4. Implements of the same character so far as the edge and sides are concerned, but having the butt end reduced in width so as to produce a square shoulder on each side of the blade. In some this reduction in width extends more than half the length of the blade, so as to produce a T-shaped form. These shorter specimens are the most common. This form appears to be peculiar to Burma. One of them has been figured by the Society of Antiquaries (Proc. N.S. vol. ii. 96).

In some cases the lashings used to fasten them to their hafts have left traces on the stone. The implements are usually picked up on the surface of the hills, in the fields, or clearings made for cultivation, and not in the plains. Mr. Theobald seems inclined to doubt whether, without the use of iron also, those who made these implements could have effected clearances in the gigantic forests of Pegu; but it may be urged against this view that by calling in the aid of fire the efficiency of such tools is almost as great as if they had been formed of metal, and it is difficult to conceive a people in possession either of bronze or iron bestowing the necessary time and trouble on the fashioning of stone tools, when those of metal were at their command, which, whether fire were employed in the clearance or no, were for general purposes so much more effective. If the makers of these stone tools had been in possession of other means for clearing the hill sides, then Mr. Theobald would be inclined to regard the stone relics as agricultural implements used in hand agriculture, at the end of sticks, as a kind of spade, to form the shallow holes for the cultivation of "hill rice." If not explained in this manner, he argues, we must regard them as weapons of the chase and war, though this use is, he thinks, negatived by their thoroughly inefficient character for such purposes. To this may be objected, first, that the material of which they are usually formed is basalt, a stone constantly used as a material for cutting tools; secondly, that the presence of the square shoulders, so like those on the horn sockets for hatchets of the Swiss Lake-dwellers, seems to testify to the tools having been used as adzes or axes, or possibly chisels; and thirdly, that if they had been required merely for hoeing or digging, the trouble of grinding and polishing might and would have been saved. We will only add that the paper is a valuable contribution to our knowledge of Eastern Neolithic implements, and that our present remarks are, like those of Mr. Theobald, "merely tentative, and designed to elicit additional information."

J. EVANS

M. FIZEAU'S EXPERIMENTS ON "NEWTON'S RINGS"

A COMPARISON of the values given by Professor Ångström (in his magnificent *Recherches sur le spectre solaire*) for the wave-lengths corresponding to the two principal components of Fraunhofer's line D, with some observations made eight or nine years ago by M. Fizeau, not only reveals a remarkable agreement between the results of these two distinguished investigators, but yields one of the most striking confirmations of the truth of the undulatory theory of light that recent optical research has afforded.

The experiments of M. Fizeau to which we refer were, essentially, the following. He produced the phenomenon of "Newton's rings," by laying a convex lens of very long focus upon a piece of glass with plane parallel surfaces, and illuminating the combination by the yellow flame of spirit of wine containing a little common salt. The lens was so arranged that it could either be made to touch the glass plate or be separated a short distance from it, its position being regulated by a micrometer screw. On gradually separating the lens from the glass plate, the rings were seen to contract and move in towards the centre of the lens, where they successively disappeared, while their place was supplied by fresh rings which made their appearance at the circumference of the lens. So far, all was in accordance with what was well-known before. But M. Fizeau found that when the phenomenon was observed with sufficient care, nearly 500 rings could be counted, flowing inwards one after another, but that after about this number the rings ceased to be visible, the surface of the glass showing a nearly uniform illumination all over instead of a sharply defined alternation of light and dark bands. When, however, the distance between the lens and the glass plate was further increased the rings re-appeared, getting gradually more and more distinct, until when nearly another 500 had passed they had become as sharp as at first; but a still further increase of distance caused them again to become confused, and they ceased a second time to be discernible at about the 1,500th. With a still greater separation of the glasses, however, they reappeared again, and became quite sharp at about the 2,000th, after which they for a third time got gradually confused and became indistinguishable at about the 2,500th.

So the phenomenon went on, the stream of rings inwards towards the centre of the lens, followed by fresh ones from the circumference, continuing as the lens was moved further and further away from the glass plate; but the succession of rings was not uniform, but broken up into batches of about 1,000 each, separated by short intervals of confusion in the way that has been described. The rings did not finally cease to be distinguishable until *fifty-two* such batches had been counted, and the two glasses were at a distance of about fifteen millimetres (more than half an inch) from each other.

This remarkable phenomenon of the alternate periods of distinctness and confusion of the rings is easily explained, as M. Fizeau points out, when we remember that the light employed was not strictly homogeneous, but consisted of two portions of nearly, but not quite, equal degrees of refrangibility. If either of these two constituent parts of the light had been used by itself, it would have produced a set of rings, but the rings of one set would have been a very little larger than the corresponding rings of the other. Hence if the two sets of rings are put together (as they were in Fizeau's experiment), they will nearly, but not quite, fit each other. If we examine a few rings at the centre, when the two glasses are in contact, they will appear to coincide precisely; but if they are traced to a sufficient distance from the centre, the coincidence is seen not to be exact. For although the *twentieth* ring (say) of one set is not perceptibly bigger than the twentieth ring of the other set, the *five-hundredth* of one set is perceptibly bigger than the five-hundredth of the other, and, when put upon it, falls almost exactly halfway between the five-hundredth and five-hundred-and-first of this set. Consequently, at about this part of the phenomenon, the bright spaces of one set of rings will occupy the same position as the dark spaces of the other set, and they will mutually obliterate each other. But since the *thousandth* ring of one set is nearly the same size as the thousand-and-first of the other, the two sets of rings will appear to fit each other again about this point; the *fifteen-hundredth* of the first set, however, is larger than the fifteen-hundred-and-first of the second set, but not so large as the fifteen-hundred-and-second; and hence, at about the position of this ring, the rings of the two sets will overlap each other, and mutually efface each other's outlines. And, carrying such considerations further, it is evident that the apparent coincidence and overlapping of the two systems of rings would recur alternately at regular intervals.

In order to simplify this explanation, we have tacitly assumed the lens to be so large that several thousand rings could be seen between its centre and its circumference. Practically, this would be impossible; but, by gradually separating the lens from the plane glass, we can, as it were, draw in towards the middle the rings which, with a larger lens, would be formed at a great distance from the centre.

Now, according to the explanation which the undulatory theory gives of the formation of "Newton's rings," the distance by which the interval between the glasses must be increased, in order that a given ring may come into the position previously occupied by the next smaller ring, must be equal to half the wave-length of the kind of light used for the experiment; and the distance of 0·28945 millimetres, through which, as M. Fizeau found by actual measurement, it was necessary to vary the space between the glasses, in order to make the rings go through one of the recurrent periods above described, that is to say, pass from sharpness to confusion and become sharp again, must contain just one more half wave-length of one portion of the light by which the rings were formed than it does of the other.

This brings us to the point of contact between M. Fizeau's observations and those of Prof. Ångström, to which we referred at the beginning. According to the latter, the wave-lengths of the two principal constituents of the light emitted by a flame containing the vapour of sodium (such as the flame employed by M. Fizeau) are respectively—

Millimetres
0·000589513
and 0·000588912.

Now, if we divide 0·28945 by half the former of these numbers, we get as the quotient 982; and if we divide it by half the second, we get as the quotient 983. That is to say, we find, precisely as the undulatory theory requires, that the distance measured by M. Fizeau contains exactly one more half wave-length of the more refrangible constituent of the light of a sodium-flame than it does of the less refrangible part. And, moreover, if we calculate, from Ångström's determination of the wave-lengths, the number of rings which must intervene between the positions of greatest confusion and greatest distinctness, we find 491 of the one set and 491½ of the other, which agrees entirely with M. Fizeau's estimated round number 500.

G. C. FOSTER

THE NEW AUSTRALIAN MUD-FISH

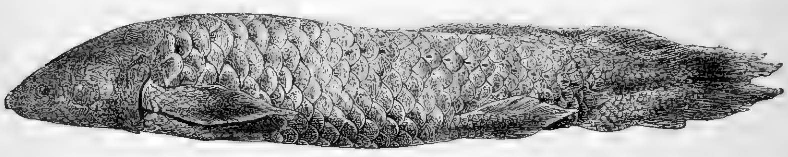
IN his well-known essay upon the arrangement of the extinct fishes of the Devonian epoch, published in the Memoirs of the Geological Survey* Professor Huxley, after showing that the *Polypterus* of the African rivers is probably the descendant of the Crossopterygian Ganoids with rhomboidal scales, continues as follows :—

"It is singular that while the line of the rhombiferous *Crossopterygidæ* has so distinct a modern representative, the cycliferous *Crossopterygidæ* seem to have died and left no issue at the end of the Tertiary epoch. But, without wishing to lay too much stress upon the fact, I may draw attention to the many and singular relations which obtain between that wonderful and apparently isolated fish, *Lepidosiren*, sole member of its order, and the cycloid glyptodipterine, ctenodipterine, phaneropleurine, and cœlacanth *Crossopterygidæ*. *Lepidosiren* is in fact the only existing fish whose pectoral and ventral members have a structure analogous to that of the acutely lobate paired fins of *Holoptychius*, of *Dipterus*, or of *Phaneropleuron*, though the fin-rays and surface-scales are still less developed in the modern than in the ancient fish. The endoskeleton of *Lepidosiren*, again, is as nearly as possible in the same condition as that of *Phaneropleuron*, and is more nearly similar to the skeleton of the Cœlacanths than that of any other recent fish ; while perhaps it is not stretching the search for analogies too far to discover in the stiff-walled lungs of *Lepidosiren*, a structure more nearly representing the ossified air bladder of the Cœlacanths than any with which we are at present acquainted, among recent or fossil fishes. Furthermore, *Lepidosiren* is the only fish whose teeth are comparable in form and arrangement to those of *Dipterus*. Though *Lepidosiren* may not be included among the Crossopterygidæ, nor even in the order of the Ganoids, the relations just pointed out are not the less distinct ; and perhaps they gain in interest when we reflect that while *Polypterus*, the modern representative of the rhombiferous Crossopterygidæ, is that fish which has the most completely lung-like of all air-bladders ; *Lepidosiren*, which has been just shown to be, if not the modern representative of the cycliferous Crossopterygidæ yet their 'next of kin,' is the only fish which is provided with true lungs. These are unquestionable facts. I leave their bearing upon the great problems of zoological theory to be developed by every one for himself."

In this remarkable passage, written some ten years ago, we may almost say that Prof. Huxley prophesied the discovery, announced in these columns some weeks since,† of the new Australian Mud-Fish, which appears to unite the dentition and other peculiarities of some of the extinct Crossopterygians with the external form of *Lepidosiren*, and thus to connect what, in the opinion of some naturalists, are two very widely separated forms of the order Pisces. Since the announcement of this discovery appeared, a paper has been read before the Zoological Society of London, containing a preliminary account of this wonderful fish, by Mr. Gerard Krefft, the curator and secretary of the Australian Museum, Sydney. Mr. Krefft proposes to call it *Ceratodus forsteri*, "after the Hon. William Forster, M.C.A., its discoverer."

The general form of *Ceratodus forsteri*, and its striking resemblance to *Lepidosiren*, will be at once seen by the accompanying figure, which has been reduced from one of the photographs forwarded to England by Mr. Krefft. The length of the specimen described (which, at the time the paper was written, was the only individual yet obtained) was about three feet ; it has a broad flat head, small eyes, and four limbs in the shape of flappers. The body is stated to be covered with large cycloid scales, ten rows on each side. A large gill-opening in front of the pectoral limb contains well developed branchiæ, but their accurate examination was not possible, on account of the bad condition of the specimen. A rather large pair of nostrils, situated just below the upper lip, communicates by a short tube with the roof of the mouth.

The skeleton of this fish is partly ossified and partly cartilaginous, the vertebræ being pure cartilage, and the ribs hollow tubes, filled with cartilaginous substance. The palate and upper part of the skull are bony, and the head is covered by two large scales. The tongue is very small, and is attached to what appears to be a large hyoid bone, ossified externally. The rays which support the dorsal and caudal fin consist of hollow tubes filled by cartilage. In the upper jaw are two large teeth, which Mr. Krefft terms incisors, and which are obviously the representatives of the peculiar teeth in the corresponding position in *Lepidosiren*.* Behind these are dental plates, divided on each side into six tooth-like projections. The lower jaw is provided with similar dental plates, but has no teeth in front ; the rami are joined only by a tough skin.



CERATODUS FORSTERI, THE NEW AUSTRALIAN MUD-FISH

Such is an abstract of Mr. Krefft's preliminary notice of this strange animal, which is certainly one of the most remarkable zoological novelties that Australia (that land of wonders) has yet produced. It is singular, indeed, that a creature like this, which appears to have been long well known to the squatters of Queensland, should have hitherto altogether escaped the observation of naturalists. It is said to have flesh of the colour of salmon, and to be excellent eating, so that the settlers have named it the "Burnett," or "Dawson salmon," from the two Queensland rivers in which it is principally found. The native name is given by Mr. Krefft as *Baramoonda* or *Baramoondi*. The fish is stated to attain sometimes a length of six feet and upwards.

* Decade x., 1861.

† See NATURE, No. 28, Vol. ii. p. 38.

* See Dr. Cobbold's discussion of these teeth, in his article on the cranium of *Lepidosiren* : Proc. Z.S., 1862, p. 129.

As regards the correct position of the *Ceratodus forsteri* in the "Systema Naturæ," we must, of course, wait until more specimens are procured for the examination of competent naturalists, the single example in the Australian museum being in an incomplete condition, from the internal organs having been removed. Mr. Krefft calls it a "gigantic amphibian," not being aware probably that all the best authorities now follow Johann Müller in classing *Lepidosiren* as a fish. It is, however, certain that, as Dr. Günther pointed out at the meeting of the Zoological Society when Mr. Krefft's paper was read, this fish must either be placed, along with *Lepidosiren* and its African representative *Protopterus*, in the order Dipnoi, or that it must form of itself a new division of the Ganoid fishes. We must know more of its internal structure, and in particular of the organs of circulation, before this question can be decided. Mr. Krefft has referred the fish to the genus *Ceratodus*, a name established by Agassiz in his "Poissons Fossiles" for the indication of certain teeth which were then supposed to be those of some kind of shark. Dr. Günther, our best living authority on the class of fishes, is, I believe, of opinion that, so far as the structure of *Ceratodus* is known, there is nothing to show that Mr. Krefft's decision is wrong, though it would appear to me to have been better to have proposed a new generic name for this animal.

In conclusion, I may express a hope that this short notice may have the effect of calling the attention of some of the colonists of Queensland to the wonderful nature of this relic of the Devonian epoch that is now swimming about beneath their noses, and that they will cease, for the present at least, to kill it and eat it as "salmon." Any specimens that may "rise to their fly" should be carefully kept out of the way of the cook, preserved in alcohol and transmitted to the British Museum or some other scientific institution. When the existence of *Ceratodus forsteri* becomes more widely known, there will be no lack of applicants for examples of it.

P. L. SCLATER

NOTES

THE Syndicate appointed by the University of Cambridge to consider the question of the manner in which provision may be made for the establishment of a Professorship of Physical Science, and increasing the facilities for instruction in it, have again reported to the Senate. It may be remembered that the former report, after having been discussed in the Schools, was referred back to the Syndicate by the Council. The present report, however, only differs in one important point from the former, in recommending that the increase in the tax levied upon the M.A. members of the University should be temporary instead of permanent. It had been hoped by many that the Syndicate would have taken courage from the general tone of the debate, have cancelled their former report, and proposed some bolder and more thorough measure. It is, however, not very probable that the University will accept the report. Several influential members of the Syndicate have not signed it; and there appears to be a growing feeling in Cambridge that, notwithstanding the obvious evil of delay, to postpone for a few months the appointment of a Professor would be better than to carry at once a temporary and unsatisfactory scheme.

THE Council of the Society of Arts at their meeting on Monday last, awarded the Albert gold medal for the present year, to M. F. de Lesseps, "for services rendered to arts, manufactures, and commerce, by the realisation of the Suez Canal."

WE regret to learn that Baron Liebig continues dangerously ill. He has recently submitted to two operations for a very painful abscess in the shoulder, and continues very weak, but perfectly clear and cheerful, although believing that death is near.

THE new lectures on physiology at Trinity College, Cambridge, by Prof. Foster, will, we understand, be open to all members of the University, so that this liberal act on the part of the college is practically equivalent to the foundation of a professorship of physiology in the University.

THERE will be an examination at St. Peter's College, Cambridge, on Tuesday, June 14, for a Natural Science Scholarship, of the value of 60*l.* per annum. It will be open to all persons who may desire to enter at the University. The subjects are chemistry, comparative anatomy, physiology, and botany. Names of candidates must be sent a week previously to Rev. J. Porter, tutor of the college, from whom further information may be obtained.

AT the meeting of the French Academy of Sciences, held on the 30th ult., Mr. Joule was elected a correspondent in the Physical section by 32 votes out of 43. Of the remainder, Professor Lloyd obtained eight, and Professors Angström, Dove, and Volpicelli one each.

THE Senate of the Queen's University in Ireland has unanimously passed a resolution conferring the honorary degree of Doctor in Science on Prof. William King, in recognition of his scientific attainments.

WE learn from the *Moniteur Scientifique*, that M. R. Radau has been charged with a commission from the French Minister of Instruction to visit Germany, for the purpose of studying the organisation for instruction in the higher mathematics in the principal universities of that country, and prepare a report.

A MONUMENT to John Kepler, at Weil der Stadt, the birthplace of the great astronomer, will be uncovered on the 24th inst. Subscriptions have been received from all parts of Germany, France, Russia, and even North America.

ON Friday, May 26, Dr. Carpenter delivered a lecture on the Physical and Biological Conditions of the Deep Sea, in the Senate House, Cambridge. His remarkably lucid and interesting account of the results of the late expeditions, illustrated by some beautiful diagrams, was listened to with great attention by a very large audience, and at the conclusion, the Master of Christ's College (who occupied the chair in the unavoidable absence of the Vice-Chancellor) proposed, and Prof. Sedgwick seconded, a vote of thanks to the lecturer, which was carried with enthusiasm. The latter made some remarks upon the bearing of Dr. Carpenter's discoveries upon Geology, which showed that notwithstanding the burden of eighty-five years, the old fire was still burning brightly.

DR. HASSKARL, formerly superintendent of the Botanic Gardens, and introducer of the Cinchona plant into Java, publishes a monograph of the Indian *Commelinaceæ*, especially those of the Indian Archipelago, with a few other species.

WE have received papers of Port Louis, Mauritius, for April 9th, containing a report of the meeting of the Meteorological Society, held March 24, when a valuable paper was read "On the Origin of Storms in the Bay of Bengal," by the secretary, Mr. C. Meldrum, with special reference to the monsoons and cyclones of the Indian Ocean.

THE last volume of the "Transactions of the Linnean Society," just published, contains Mr. Carruthers's long-expected paper "On Fossil Cycadean Stems from the Secondary Rocks of Britain."

MR. CHARLES T. BROWN, of the Geological Survey of Demerara, has lately returned from a journey of three months' duration in the interior. He has examined the Potaro, Siparunie, and Burroburro rivers, and the country beyond the heads of the latter two, which he finds to be table-land, composed of slightly-inclined beds of sandstone and conglomerate. On the Potaro river he met with a magnificent fall, hitherto unknown.

It is formed by the river falling from a table-land 1,375 feet above the sea, perpendicularly, in an unbroken fall of about 900 feet. The river is 100 yards wide, and from 10 to 15 feet deep in its deepest parts. It is with much regret we hear that the Combined Court of this colony have determined that this survey shall be discontinued.

IN the *Artisan* for June is an article by Mr. John Scott Russell, on "International Communication by Railway Steamships," a mode of performing the Channel transit which he has long advocated. The real point of difficulty he states to be this: Dover Harbour is the property of the Government; Calais Harbour is also the property of the French Government. He believes that if the two Governments lay their heads together, and simply make their harbours accessible, which can be done at a moderate expense, a great international communication can be easily established.

IN his annual address as President of the Canadian Institute, the Rev. Wm. Hincks makes use of the following argument in opposition to the Darwinian theory of Natural Selection:—"Nothing is to me more evident than that both seemingly permanent specific and higher differences, and varieties which have no pretensions to permanence, depend on the comparative development of different elements of a common plan; from which it seems to follow both that the non-existence from the commencement of living nature, of all the distinct plans of structure is in the highest degree improbable, and that the tendency of development, sometimes in one direction, sometimes in another, among the same primitive elements, must produce a harmonious system; whilst the preservation of the forms best adapted to a situation amongst a great number of variations arising without order must produce a confused mass of objects having no regular relations and incapable of being reduced to a common system. Which of these prevails in nature I cannot for a moment hesitate in deciding, and consequently I must maintain that, if there is variation, it must be within definite limits, and according to a fixed plan, so as to maintain a uniform order and harmony in the whole system."

A REMARKABLE *mirage* was seen at Ostend on May 19. Ships riding in the roads in the horizon were reflected in the sky as by a gigantic mirror; a brig, a steamer, and several fishing-boats appeared to have other similar vessels attached to the summits of their masts in a reversed position. The phenomenon lasted through the whole of the afternoon and evening, the wind being light from the N.N.E. From 5 to 6.30 P.M. the French coast was visible as far as Dunkirk, the houses being quite distinct, and the *dunes* appearing suspended in the air at a height of several metres, and somewhat moved in position towards the N.W. The port of Niewport seemed so near that the bridge was distinctly visible.

IN the last number of the *Revista das Obras Publicas* (Review of Public Works), Senhor C. A. Beirao mentions an interesting phenomenon of terrestrial refraction, observed by him on the evening (or afternoon, *vespera*) preceding the storm which caused such damages on the Tagus on Easter Day. Here is what Senhor Beirao says about the phenomenon:—"From the house in which I live, in the Rua (street) of S. Joao da Praça,* only about a third of the upper part of the Bugio Lighthouse is to be seen, all the rest is interrupted by the roofs of the buildings in the Praça do Commercio (called by the English 'Black Horse Square,' where all the public departments stand). On that occasion (half-past four o'clock P.M. on Saturday of Alleluia) as I by chance directed my spy-glass towards the tower (*i.e.* of the Bugio), I remarked that not only the latter was completely in view, but also the surface of the water to a distance of many metres on this side the Tower, which indicated, with respect to the latter, an elevation of fifty to sixty metres, at least, over the line of normal vision."

* This street is about four-and-a-half miles from the said Bugio lighthouse.

THE second part of the Proceedings of the Bristol Naturalists' Society contains a notice, by Dr. H. E. Fripp, of recent observations of Amœbæ and Monads by Greef and Cienowski, in which he describes the species of Amœbæ and Rhizopods recently discovered living in the earth; a paper by S. H. Swayne on the Scales and other tegumentary organs of Fish; an analysis by Mr. Sanders, of the Report on Theories of Elevation and Earthquakes, presented to the British Association by the late Professor Hopkins; a note by a lady associate on a novel application of tea leaves for promoting the growth of plants; and a paper on the Descent of Glaciers, by the Rev. Canon Moseley, in which he refers the motion of glaciers to a succession of small alternations of temperature, causing expansion and contraction with a cumulative effect. There is also a paper, by Mr. Stoddart, on Rain-water collected in Bristol, showing the presence of considerable amounts of saline material in the water.

AN icono-photograph album, containing numerous figures of the appearances presented by sections of the nervous centres, has just been presented by Dr. Ducheune, of Boulogne, to the French Academy of Medicine. He states he has obtained excellent results from sections of the great sympathetic nerve, the spinal ganglia, the spinal cord, and of the medulla oblongata when magnified from 8 to 500 times. The plan was suggested some years ago by Dr. Ducheune himself; but it was found that the photographs obtained in the ordinary method were not persistent. He therefore fixed them on stone by a process he terms photo-autography, the details of which, however, he does not communicate. It is satisfactory to find him stating that the results of his experiment and photographs only confirm the substantial accuracy of the beautiful drawings made by Dr. Lockhart Clarke on the central parts of the nervous system, and especially upon the medulla oblongata. In his later experiments Dr. Ducheune has adopted Dr. Clarke's mode of preparation with chromic acid and carmine. He states that certain micrographic details come out with wonderful clearness in the photographs, and that by this means some important additions may be made to our knowledge. Thus he has ascertained that in the white substance of the medulla oblongata there are a large number of very small nerve tubules (0^{mm}, 0033) diameter mingled with others of average and of large diameter 0^{mm}, 0 1 to 0^{mm}, 0 2 and ·0·3.

FROM the proceedings of the Institute of Lombardy, reported in the *Imparziale* of the 16th May, we extract the following results of the important experimental researches of Prof. Mantegazza on the action of the essences of flowers on the production of atmospheric ozone. 1. The essences of mint, turpentine, cloves, lavender, bergamot, anise, juniper, lemon, fennel, nutmegs, cajeput, thyme, cherry laurel, in contact with atmospheric oxygen in light, develop a very large quantity of ozone, equal if not superior in amount to that produced by phosphorus, by electricity, and by the decomposition of permanganate of potash. 2. The oxidation of these essences is one of the most convenient means of producing ozone, since even when in very minute quantity they can ozonise a large quantity of oxygen, whilst their action is very persistent. 3. In the greater number of cases the essences, in order to develop ozone, require the direct rays of the sun; in a small number of cases they effect the change with diffused light; in few or none, in darkness. 4. In some cases, however, the action just commenced in solar light was found to persist to some extent when the essence was placed in darkness. 5. In some cases a vessel perfumed with an essence and afterwards thoroughly washed with alcohol and perfectly dried, could still develop a proportionate quantity of ozone, provided that it retained a slight odour of the essence. 6. The essences that developed the largest quantity of ozone were those of cherry laurel, palmarosa, cloves, lavender, mint, juniper, lemons, fennel, and bergamot; those that gave it in less quantity were anise, nutmeg, cajeput, and thyme. 7. Camphor, as an ozonogenic agent, is inferior to all the above-named essences. 8. Eau de Cologne, honey water, and other perfumes, or aromatic tinctures, develop a proportionate quantity of ozone when they are exposed to the direct rays of the sun. 9. The flowers of the narcissus, hyacinth, mignonette, heliotrope, lily of the valley, &c., develop ozone in closed vessels. Flowers destitute of perfume do not develop it, and those which have but slight perfume develop it only in small quantities. As a corollary from these facts the professor recommended the use of flowers in marshy districts and in places infected with animal emanations, as the powerful oxidising influence of ozone may destroy them. The inhabitants of such regions should surround their houses with beds of the most odorous flowers.

THE fourth part of the "Researches undertaken in the Physiological Laboratory of Wurzburg," edited by Dr. Richard Gscheidlen, has been published. It contains a kindly notice of the life of Albert von Bezold, so untimely snatched away by death; a most profound investigation on nerve and muscle electricity, an abstract of which, we fear, would be unintelligible to our readers, by Worm-Müller, of Christiania; an essay on the Calabar bean, by the editor, and some remarks on the movements of the Iris, by Dr. Engelhardt. In this last it is shown that atropine paralyses the extremities of the third nerve, whilst Calabar bean acts as an irritant upon them, and he holds that there is a ganglionic nervous centre or organ imbedded in the iris, and intercalated between the fibres of the third and the sphincter which acts as an inhibitory centre on the sympathetic.

PRIZE MEDALS OF THE ROYAL GEOGRAPHICAL SOCIETY

THE Royal Geographical Society of London having taken into consideration the fact that a knowledge of geographical facts, and still more a knowledge of the science of geography, is not so common among educated persons as it ought to be, determined, about two years ago, to offer prizes in the shape of gold and bronze medals, to be competed for by boys from certain selected public schools. The principle which governed the choice of the schools, was the number of boys who were receiving education therein; no school having less than 200 boys being chosen for the competition.

An effort was made, at the time that the matter was under discussion, to get girls admitted as candidates. It was, however, objected that there were no public schools for girls which could be invited to compete, and it was also said that it might be well to see how the experiment would work with boys before inviting girls to the competition.

These questions being settled, the next thing to arrange was the manner in which the examinations should be conducted. It was obvious that to bring a number of boys from the various schools scattered all over the country to London, would be practically impossible; and it was equally obvious that some process of selection would have to take place in the schools themselves, so that the best boys only should have their papers sent to the examiners appointed by the Council of the Royal Geographical Society. It was therefore determined that the subjects of examination should be divided into Political Geography and Physical Geography, and that no candidate should be permitted to be examined in both subjects at the same time. Moreover, not more than four candidates in each subject were allowed to take the papers; these four, of course, having been selected by the masters of the various schools from among those most likely to pass. The Council of the Geographical Society could not undertake to direct any preliminary examination—that had to rest entirely with the authorities of the various schools.

It was ultimately determined that the examination should take place by means of papers of questions, which should be sent in sealed packets to the Head Masters of the selected schools; and that these papers should be given out and worked simultaneously at all the schools. The superintendence of the examinations was to be done by a master of each school, who was to be present during the whole time the paper was worked. In order to ensure, as far as possible, the strict fulfilment of the conditions under which the examination was to take place, a declaration was required to be signed by all the masters who were present while the work was going on. This declaration set forth that the candidates worked the papers without assistance, and that there were no globes or maps in the room where they were written. It also declared that the specified masters were present during the whole of the time.

Thirty-seven schools, containing in the aggregate about 12,700 boys, were invited to compete at the first examination. These schools included the nine schools of the Royal Commission of 1864, and all others in England, Scotland, and Ireland which, according to the latest edition of the "Public Schools Calendar," contained not less than 200 boys.

Twenty-one of the invited schools sent candidates; no school being permitted to send more than eight boys, four candidates in the subject of Physical, and four in that of Political Geography. Many schools did not send the maximum number. In fact, four schools had only one candidate each; and out of the twenty-one schools, only four presented the highest number of candidates allowed. Last year forty-two schools were invited to take part in the examinations, but only nineteen sent candidates.

The papers set, both in Physical and Political Geography, bore a remarkable resemblance to each other, and in looking over the syllabus published by the Geological Society, it is impossible not to feel that the line between the two is very feeble, and, in some instances, indefinitely indicated. The special subject appointed for next year is North America.

The examiners appointed for the first year were the Rev. W. G. Clark, F.R.G.S., Public Orator of the University of Cambridge, for Political, and Mr. A. R. Wallace, F.R.G.S., for Physical Geography; and for the second year the Dean of Chester for Physical, and Mr. Wallace for Political Geography.

The successful candidates received their awards last year and this at the anniversary meetings of the Royal Geographical Society.

Rossall School and the Liverpool College have been very distinguished in the examinations. In the first year Rossall carried off both the gold and the bronze medals for Physical Geography; and in the second year the bronze medal for Physical, and the gold medal for Political Geography, both fell to pupils of the same school. The Liverpool College gained the gold medal for Political Geography in the first year, and the gold for Physical, and bronze for Political, in the second year. Honourable mentions have also been gained by the pupils of various other schools.

A very remarkable fact, to be noticed as the result of these examinations, is that the schools which obtained the prizes are not those which the general public is accustomed to look upon as the leading schools of England; while Eton, Harrow, and Rugby are among those who have, as yet, sent no candidates at all. This is the more noticeable as, to Englishmen, the travellers of the world, and the subjects of a monarch on whose dominions the sun never sets, it does appear as if geography ought to be a subject of vast importance instead of being one in many cases almost neglected. Sir R. Murchison, in presenting the medals at the recent meeting of the Royal Geographical Society, hoped that Eton, Harrow, Rugby and other great schools might, in future years, send candidates, "for, without geography, a man cannot be said to be educated at all." Westminster School, it may be stated, to the disgrace of the rest, is the only public school represented in the competition, and has twice had honourable mention.

The Royal Geographical Society has made a wise step in inaugurating this movement, which will give, it is to be hoped, a powerful stimulus to the popular study of geography. The learned societies are at present too much dissociated from the general education of the country. Science has so few votaries among the bulk of the population, that a knowledge of scientific facts, with anything like accuracy, or an acquaintance with scientific methods of working, is almost totally absent from the education of the majority. The scientific man is still to too many persons a species of magician, arriving at his information in occult ways, not to be penetrated by the ordinary observer.

Government is called upon from all sides to do this and that in the matter of education. But Government is slow to move, and is quite sure not to please everybody when it does. In the meantime let scientific societies, each anxious for the spread of knowledge on its own subject, take example by the Royal Geographical Society. Let prizes and honourable mentions be offered, let them be somewhat difficult of attainment, and let the distinction be matter of public award; and it will soon be seen that the scientific education of the country will have received a healthy and vigorous impulse, which will do much to spread the desired instruction through all classes of the nation.

J. A. CHESSAR

ON THE PROGRESS OF BOTANY IN 1869

II.

WITH regard to the succession of races which have undergone a complete specific change through successive geological periods, we have not in plants, in as far as I am aware, any such cases of "true linear types or forms which are intermediate between others because they stand in a direct genetic relation to them," as Professor Huxley appears to have made out in favour of the pedigree of the horse in his last anniversary address to the Geological Society. And I may, in regard to plants, repeat with still greater emphasis his dictum, that "it is no easy matter to find clear and unmistakable evidence of filiation among fossil animals; for in order that such evidence should be quite satisfactory, it is necessary that we should be acquainted with all the most important features of the organisation of the animals which are supposed to be thus related, and not merely with the fragments upon which the genera and species of the palæontologist are so often based." The difficulty is much greater in the case of fossil plants; for instead of bones, teeth, or shells, portions of internal or external skeletons, the parts preserved to us from the Tertiary period are generally those least indicative of structural organisation. Mr. Carruthers has recently (*Geological Magazine*, April and July 1869, and *Journal of the Geological Society*, August 1869) adduced satisfactory evidence of the close affinity of *Sigillaria* and the allied genera of the coal-period with the living Lycopodiaceæ, formerly suggested by Dr. Hooker, but, as he informs me, no connecting links, no specimens indeed of the whole order, have as yet been found in any of the intermediate Cretaceous or Tertiary deposits. Among the latter the presence of numerous types, to which we may plausibly refer as to the ancestors of living races, is established upon unimpeachable data; but I have been unable to find that a single case of authentic pedigree, as successively altered from the Cretaceous through the abundant deposits of the Eocene and Miocene period to the living races, has been as yet as satisfactorily made out as that of the absolute identity of *Taxodium* and others above mentioned, although I feel very little doubt that such a one will yet be traced when our palæontologists will have ceased to confound and reason alike upon the best proved facts and the wildest guesses. Our late distinguished foreign member, Professor Unger, whose loss we have had so recently to deplore, had indeed, shortly before his death, published, under the name of "Geologie der Europäischen Waldbäume, part I. Laubhölzer," no less than twelve tabular pedigrees of European forest races; but it seems to me that in this, as in another of the same eminent palæontologist's papers to which I shall presently have to refer, his speculations have been deduced more freely from conjectures than from facts. There is no doubt that the presence of closely allied representatives of our Beeches, Birches, Alders, Oaks, Limes, &c., in the Tertiary deposits of central and southern Europe is fully proved by inflorescences and fruits as well as leaves; but how can we establish the successive changes of character in a race when we have only the inflorescence of one period, the fruit of another, and the leaf of a third? I do not find a single case in which all three have been found in more than one stage, and by far the great majority of these fossil species are established on the authority of detached leaves or fragments of leaves alone.

Now let us consider for a moment what place a leaf really holds in systematic botany. Would any experienced systematic botanist, however acute, on the sole examination of an unknown leaf, presume to determine, not only its natural order and genus, but its precise characters as an unpublished species? It is true that monographists have sometimes published new species founded on specimens without flower or fruit, which from collateral circumstances of habitat, collector's notes, general resemblance, &c., they had good reason to believe really belonged to the genus they were occupied with; but then they had the advantage of ascertaining the general *facies* derived from insertion, relative position, presence or absence of stipular appendages, &c., besides the data supplied by the branch itself. And with all these aids even the elder De Candolle, than whom no botanist was more sagacious in judging of a genus from general aspect, was proved to have been in several instances far wrong in the genus, and even order, to which he had attributed species described from leaf specimens only. Palæontologists, on the other hand, have, in the majority of these Tertiary deposits, had nothing to work upon but detached leaves or fragments of leaves, exhibiting only outward form, venation, and, to a certain degree, epidermal structure, all of which characters may be referred to that class which Professor Flower, in his introductory lecture at the Royal College of Surgeons in February last, has so aptly designated as *adaptive*, in contradistinction to essential and fundamental characters. They may, when taken in conjunction with relative individual abundance, assist in forming a general idea of the aspect of vegetation, and thus give some clue to certain physical conditions of the country; but they alone can afford no indication of genetic affinity, or consequently of origin or successive geographical distribution.

Lesquereux, in speaking of Cretaceous "species, or rather forms of leaves," observes in a note to his paper on Fossil Plants from Nebraska (*Silliman's Journal*, vol. xlvi. July 1868, p. 103), that "it is well understood that when the word *species* is used in an examination of fossil plants, it is not taken in its precise sense, for indeed no *species* can be established from leaves or mere fragments of leaves. But as palæontologists have to recognise these forms described and figured, to compare them and use them for references, it is necessary to affix to them specific names, and therefore to consider them as species." But the investigators of the Tertiary floras of Central and Southern Europe have acquired the habit, not only of neglecting this distinction, and naming and treating these forms of leaves as species equivalent to those established on living plants, but of founding upon them theories which must fall to the ground if such specific determination proves inaccurate. Nothing can be more satisfactory than such determinations as that of *Podogonium* for instance, which Professor Heer has succeeded in proving, by numerous specimens of leaves, fruits, and even flowers, some of them still attached to the branches, which I had myself the pleasure of inspecting last summer under the friendly guidance of the distinguished Professor himself. This genus of Cæsalpineæ, from its evident affinity with *Peltogyne*, *Tamarindus* and others now scattered over the warmer regions of America and Africa, and more sparingly in Asia, tells a tale of much significance as to the physico-geographical relations of the Swiss Tertiary vegetation, confirmed as it is by some other equally, or almost equally, convincing examples. But the case appears to me to be far different from the theory so vividly expounded by Professor Unger in 1861 in his Address entitled "Neu Holland in Europa;" this generally admitted theory seems to me to be established on some such reasoning as this:—There are in the Tertiary deposits in Europe, and especially in the earlier ones, a number of leaves that look like those of Proteaceæ; Proteaceæ are a distinguishing feature in Australian vegetation; *ergo*, European vegetation had in those times much of an Australian type derived from a direct land communication with that distant region.

This conviction that Proteaceæ, belonging to Australian genera, were numerous in Europe in Eocene times, is indeed regarded by palæontologists as one of the best proved of their facts. They enumerate nearly 100 Tertiary species, and most of them with such absolute confidence that it would seem the height of presumption for so inexperienced a palæontologist as myself to express any doubt on the subject. And yet, although the remains of the Tertiary vegetation are far too scanty to assert that Proteaceæ did not form part of it, I have no hesitation in stating that I do not believe that a single specimen has been found that a modern systematic botanist would admit to be Proteaceous, unless it had been received from a country where Proteaceæ were otherwise known to exist. And, on other grounds, I should be most unwilling to believe that any of the great Australian branches of the order ever reached Europe. As this is a statement requiring much more than mere assertion on my part, I shall beg to enter into some detail, commencing with a short summary of my grounds of disbelief in European Tertiary Proteaceæ, and then examining into the supposed evidences of their existence.

The analysis and detailed descriptions I have had to make within the last few months of between five and six hundred Proteaceæ, and consequent investigation of their affinities and distribution have shown that the order as a whole is one of the most distinct and most clearly defined amongst Phanerogams. I do not know of a single plant intermediate in structure between that and the nearest allied orders, which I cannot say of any other of the large orders I have worked upon. There is, moreover, especially amongst the Nucamentaceæ, a remarkable definiteness in the majority of genera without intermediate species, whilst the whole order exhibits the greatest uniformity in some of its most essential characters, derived from the arrangement of the floral organs and the structure of the ovary and embryo, accompanied by a truly Protean foliage. All this points, in my mind, to unity of origin, very great antiquity, and long isolation in early times. And the species themselves appear to be for the most part constitutionally endowed with what I designated in my last year's address as individual durability rather than with rapidity of propagation. The order may be divided into about five principal groups, more or less definite in character, but very different in geographical distribution. First, the Nucamentaceæ (from which I would exclude *Andripetalum* and *Guevina*), which we may suppose to be the most ancient, and perhaps the only one in existence where Proteaceæ inhabited some land in direct communication, either simultaneously or consecutively, with extra-tropical Africa and Australia; for it is the only group now represented in the former. It is pre-eminently endowed with the characteristic definiteness and durability of the order. It is very natural as a whole; it has about 250 species in eleven distinct African genera, and nearly 200 species in twelve equally distinct Australian genera, no single genus common to the two countries, and the species mostly abundant in individuals in very restricted localities. In both countries it is chiefly confined to the south. Africa sends only one or two species northward, as far as Abyssinia. The Australian portion has extended to New Zealand, where it has left a single species, now quite differentiated from the Australian ones; very few species (not half-a-dozen) have reached tropical Australia; and, if ever it extended farther, no representatives have yet been discovered in America, Asia, or even in New Caledonia. The four remaining groups, constituting the Folliculares, must have all been formed since the isolation from Africa. 1. Banksieæ, two genera, with above 100 species, have the type of distribution of the Australian Nucamentaceæ, chiefly southern, local, and abundant in individuals, with three or four species penetrating into the tropics, but none beyond Australia 2. Grevilleeæ, in which the genera are somewhat less definite and the distribution more extended, have above 300 species in about eight genera, of which the greater portion are still southern and local; but yet a considerable number are tropical, and a few extend to New Caledonia, although none beyond that. 3. Embothrieæ, with about twenty-five species in half a dozen genera, form part of that southern, chiefly mountain, flora which extends from Tasmania and Victoria to New Zealand, Antarctic and Chilian America, a flora which comprises many species which we might imagine to have spread from the northern hemisphere down the Andes to Antarctic America, and thence to New Zealand and Australia, whilst others may have extended in a contrary direction; and amongst these we may conjecturally include the Embothrieæ, which in America are not found farther north than Chile; whilst in Australia, although chiefly from the southern and eastern mountains, two or three species are northern, and one or two more are found in New Caledonia, but none in the Indian Archipelago, nor in Continental Asia. 4. We have lastly the tropical form of Proteaceæ, the Helicieæ, which are but a slight modification in two different directions (modifications either of the flower or of the fruit) of the Grevillea type, probably of a comparatively recent date; and although now widely spread over South America and Asia, have, nevertheless, left representatives in the original Grevillea regions of Australia. There are nearly 100 species in about eight genera, almost all tropical or subtropical; three small genera are exclusively Australian; *Helicia* itself is Asiatic, chiefly from the Archipelago, extending, in four species, to tropical Australia; in one or two species to New Caledonia; in two or three northward to the mountains of Bengal and Sikkim; and in one species even to Japan. Two American genera, with about forty species, are represented in New Caledonia by one genuine species of each, and one of an allied genus or section; and in tropical Australia by one species showing still the Australian connection; and two small genera are, as far as hitherto known, exclusively American; and may have been there differentiated. No Helicieæ, nor indeed, as already observed, any Folliculares, have hitherto been discovered in Africa. If, therefore, Proteaceæ have really ever extended to Europe, it would naturally be in this Helicioid group that we should seek for them. As far, however, as I can learn, among the supposed century of European Proteaceæ, there is only one which palæontologists refer to it, the *Helicia sotzkiana* of Ettingshausen, founded on a single leaf, which Ettingshausen himself admits to bear much resemblance to the leaves of about twenty genera in thirteen different families; and, upon much consideration, he thinks it rather more like a *Helicia* than anything else, and therefore definitively names it as such, a decision in which it is difficult to concur.

In answer to the above negative considerations, which, after all, lead to presumption only, we are told that we have positive evidence of the existence of Proteaceæ in the Miocene, and still more in the Eocene formations of Europe, in leaves, fruits, and seeds. As none of these have been found attached to the branches nor even in sufficiently abundant proximity to be matched with anything like certainty, we must take the three separately. First, as to seeds, those referred by palæontologists to Proteaceæ are winged and samaroid, some of them probably real seeds, shaped, without doubt, like those of some *Hakeæ* and *Embothria*, but quite as much like those of several Coniferæ, or of certain genera of Meliaceæ, Sapindaceæ, and various other Dicotyledonous orders, there being no evidence of internal structure, conformation of the embryo, &c., by which alone these several samaroid seeds can be distinguished. Moreover, those figured by Ettingshausen in his paper entitled "Die Proteaceæ der Vorwelt" (Proc. Imp. Acad. Sc. Vienna, vii. 711, t. xxxi. f. 11, 12, 14, 15, and 8), have a venation of the wing very different from that of any Proteaceæ I have seen, and much more like that of a real samara of an ash. Next, as to fruits, the hard follicles or nuts of Proteaceæ are as remarkable for their durability as the capsules of so many Australian Myrtaceæ; and we should be led to expect that, where Proteaceous remains are abundant, they should include a fair proportion of fruits, as is the case with the Conifers, Leguminosæ, &c., which have been undoubtedly identified. These supposed Proteaceous fruits in the Tertiary deposits are, however, exceedingly rare. The only ones I have seen figured are: (1) a supposed Embothrium fruit figured by Heer in his Tertiary Flora of Switzerland (t. xcvii. f. 30), an outline impression, with a deficiency in the upper portion, and without indication of internal structure; if this deficiency were filled up, and the seeds inserted, as in the imaginary restoration, f. 31 (for which I see no warrant, and in which the seeds are in the wrong position), it would be something like, but to my eyes not much like, the follicle of an *Embothrium*, and quite as much like what Ettingshausen figures (t. xxxi. f. 5) as the veinless leaf of a *Lambertia*; and (2) the supposed *Persooniæ* and *Cenarrhenes* drupes figured by Ettingshausen (t. xxx.) The former, in the absence of all indication of structure, are quite as good, if not better, representations of young fruits of *Ilex*, *Myoporum*, and many others, as of *Persoonia*; and where, in figures *c* and *d* of the same plate, recent (unripe) Persoonia fruits are inserted, for comparison, with the fossil figures β, γ, and δ, it appears to me that in the latter the long point is the pedicel, and the short point the style, whilst in the former, on the contrary, the short point is the pedicel, and the long one the style. To suppose that fig. 5 of the same plant represents the fruit of a *Cenarrhenes*, which, as far as known, has always an obliquely globular drupe, requires indeed a great strain upon the imagination. I can find no other fossil Proteaceous fruit figured or described.

Lastly, with regard to leaves, necessarily the mainstay of palæontologists, I must admit that there is a certain general *facies* in the foliage of this order that enables us in most, but not in all cases, to refer to it with tolerable accuracy leafy specimens known to have come from a Proteaceous country, even without flowers or fruit; but as to detached leaves, I do not know of a single one which, in outline or venation, is exclusively characteristic of the order, or of any one of its genera. If we know the genus and section of a specimen, we may determine its species by the venation; and we may sometimes fairly guess at its genus if we know it to be Proteaceous; but that is all. Outline is remarkably variable in many species of Grevillea and others, and venation is not always constant even on the same individual. But then we are told, with the greatest confidence, that the structure of the stomata in these fossil leaves, as revealed by the microscope, proves them beyond all doubt to be Proteaceous. In reply to that, I can only refer to the highest authority on these curious organs, Hugo Mohl, who, in a very careful and elaborate memoir specially devoted to the somata of Proteaceæ, has the following passage ("Vermischte Schriften," p. 248):—"Striking as is the above-described structure of the stomata in Proteaceæ, we should, nevertheless, not be justified in regarding this as a peculiarity of this family; for all the variations which we meet with in the structure of the stomata in Proteaceæ are also to be found in plants belonging to widely distant orders."

From the above considerations, I cannot resist the opinion that all presumptive evidence is against European Proteaceæ, and that all direct evidence adduced in their favour has broken down upon cross-examination. And however much these Eocene leaves may assume a general character, which may be more frequent in Australia (in Proteaceæ and other orders) than elsewhere, all that this would prove would be, not any genetic affinity with Australian races, but some similarity of causes producing similarity of adaptive characters.

Another series of conclusions drawn by palæontologists from their recent discoveries, which appears to me to have been carried too far, relates to the region where a given species originated. The theory that every race (whether species or group of species derived from a single one) originated in a single individual, and consequently in one spot, from which it has gradually spread, is a necessary consequence of the adoption of Darwinian views; and when Mr. R. Brown ("On the Geographical Distribution of Conifers," Trans. Bot. Soc. Edin. x. p. 195) sneers at my having qualified it as a perfect delusion, he must have totally misunderstood, or rather misread, the passage he refers to in my last year's address. The expression is there specially applied to the idea of general centres of creation, whence the whole flora of a region has gradually spread, in contradistinction to the presumed origin of individual races in a single spot, which is there as distinctly admitted. The determination of where that spot is for any individual race is a far more complicated question than either geographical botanists or palæontologists seem to suppose. "Every vegetable species," as well observed by Prof. Heer, "has its separate history," and requires a very careful comparison of all the conclusions deducible as well from present distribution as from ancient remains. The very important fact that *Taxodium distichum*, *Sequoiæ*, *Magnoliæ*, *Salisburia*, &c., existed in Spitzberg in Miocene times, so satisfactorily proved by Heer, shows that the vegetation of that country then comprised species and genera now characteristic of North America; but it appears to me that the only conclusion to be drawn (independently of climate and geology) is, that the area of these species and genera had extended continuously from the one country to the other, either at some one time or during successive periods. The proposition that "Spitsberg appears to have been the focus of distribution of *Taxodium distichum*," because an accidental preservation of its remains shows that it existed there in the Lower Miocene period, would require at least to be in some measure confirmed by a knowledge of the flora of the same and preceding periods over the remainder of its present area, the greater part of which flora is however totally annihilated and for ever concealed from us. The fact that *Pinus abies* existed in Spitsberg in Miocene times, and that no trace of it has been found in the abundant Tertiary remains of Central Europe, is very instructive. It might show that that tree was of more recent introduction into the latter than the former country; but it cannot prove that it was not still earlier in some other region, whence it may have spread successively into both territories, still less that its course of dissemination was directly from Spitsberg over Northern and Central Europe. Moreover, the determination of *Pinus abies* is not so convincing as that of the *Taxodium*, resting as it does, if I correctly understand Prof. Heer's expression, on detached seeds and leaves, with a few scales of one cone, and may require further confirmation.

In the above observations it is very far from my wish to detract from the great value of Professor Heer's researches. Interested as I have been in the investigation of the history of races of plants, I have deeply felt my general ignorance of palæontology, and consequent want of means of checking any conclusions I may have drawn from present vegetation by any knowledge of that which preceded it, and the impossibility at my time of life of entering into any detailed course of study of fossils. Like many other recent botanists, I am obliged to avail myself of the general results of the labours of palæontologists, and if I have here ventured on a few criticisms, it is only as a justification of the hope that they may in some measure distinguish proved facts from vague guesses, in order that we may know how far reliance is to be placed on their conclusions.

Spontaneous generation, or Heterogeny, is a question which continues to excite much interest. It has been the subject of detailed memoirs, of violent controversies, and of popular articles in this country, and still more on the Continent; but the solution of the problems still involved in doubt does not seem to me to have much advanced since I alluded to the opposing theories of Pasteur and Pouchet in my Address of 1863. The present state of the case appears to me to be this: in the higher orders of animals every individual is known to proceed from a similar parent after sexual pairing; in most plants, and some of the lower animals, besides the result of that sexual pairing which they all are endowed with, reproduction from the parent may take place by the separation of buds, by division, or sometimes by parthenogenesis; in some of the lower Cryptogams, the first stage in which the new beings are separated from the parent is that of spores termed agamic, from the belief that they never require previous sexual pairing, although the range of these agamic races is being gradually restricted, a remarkable advance having been recently made in this direction by Pringsheim in his paper on the pairing of the Zoospores in *Pandorina* and *Eudorina*. In all the above cases, in all organised beings which in their earlier stages are appreciable through our instruments, every individual has been proved to have proceeded in some stage or another from a similarly organised parent. But there are cases where living beings, Vibrios, Bacteria, &c., first appear under the microscope in a fully formed state, in decaying organic substances in which no presence of a parent could be detected or supposed: three different theories have been put forward to account for their presence: first, that they are suddenly created out of nothing, or out of purely inorganic elements, which is perhaps the true meaning disguised under the name of spontaneous generation, a theory not susceptible of argument, and therefore rejected by most naturalists as absurd; secondly, that they are the result of the transformation of the particles of the organic substances in which they are found, without any action of parent Vibrios or Bacteria; and this appears to be what is specially termed Heterogeny; thirdly, that there existed in these organic substances germs which had proceeded from parent Vibrios and Bacterias, but too minute for optical appreciation, and that their generation was therefore normal. The supporters of Heterogeny rely on the impossibility of accounting for the appearance of the Vibrios and Bacterias in any other manner; for they say that although you treat the medium by heat in a hermetically closed vessel in such a manner as to destroy all germs and intercept all access, still these beings appear. This their opponents deny, if the experiments are conducted with proper care. So it was seven years ago, and so it is still, although the experiments have been frequently repeated in this country, in France, and in North America, almost always with varying results. All reasoning by analogy is still in favour of reproduction from a parent; but Heterogeny has of late acquired partisans, especially in Germany, among those who are prepared to break down the barriers which separate living beings from inorganic bodies.

Brown's celebrated theory of the Gymnospermy of Conifers and allied orders has been of late the subject of keen controversy. Objected to by Baillon, Parlatore, and others, it had been strongly supported by Caspary, Eichler, and lastly, by Hooker in his important Memoir on *Welwitschia*, published in our Transactions in 1863. There the question seemed to rest till last year, when two detailed papers appeared, the one contesting, the other advocating the theory. The most elaborate is without doubt that of Gustav Sperk, in the "Memoirs of the Imperial Academy of Sciences at St. Petersburg." He gives a very fair *résumé* of all that had been published on the subject, and proceeds to record in detail his own observations on the structure and anatomy of the flower in a considerable number of Coniferæ, of *Ephedra alata*, *Gnetum latifolium*, and two species of *Cycas*, illustrated by well-executed analytical figures. He endeavours to prove, chiefly by their anatomy and development; that the coating which encloses the nucleus is carpellary, not ovular, of independent origin, always free, and often earlier developed than the nucleus—that what is wanting in gymnosperms is not the ovarium or carpellary envelope, but the ovular coating—that these plants are in fact gymnosperms in the sense of having naked nuclei and embryo-sacs, not naked ovules.

P. Van Tieghem, on the contrary, in the *Annales des Sciences Naturelles*, ser. 5, vol. x., considers the gymnospermy of the ovules of Conifers to be proved by the anatomical structures of the organs on which they rest. He says that, as in normal Dicotyledons, the ovules are developed from, and continuous with, the margins of carpellary leaves, but these carpellary leaves are open, variously or imperfectly developed, and constitute solitary leaves on a secondary branch in the axil of the subtending bract, this secondary branch being arrested in its development, and the carpellary leaf facing the bract; the paper is illustrated by a large number of diagrams. These two Memoirs, published simultaneously at St. Petersburg and at Paris, contain of course no reference to each other. How far each author may or may not have proved his case, I cannot now take upon myself to inquire into. Neither of them appears to have had any knowledge of the views of Professor Oliver, who in his review of Hooker's Memoir on *Welwitschia* (Nat. Hist. Review, 1863) suggests the analogy of the disputed organ with the axial developments known under the name of floral discs. Both writers, however, confirm the anomalous structure of the flower in this great class of plants, and the position of the plants themselves in many respects intermediate between the higher Cryptogams and Dicotyledons, their connection with the former being clearly shown by the researches of Carruthers and other palæontologists, and with Dicotyledons through *Welwitschia* by Hooker in his above-mentioned Memoir.

Teratology is a subject which has again risen into importance, as aiding in the history of the variations worked upon by natural selection in the formation of species. There had always been a tendency to attribute monsters and prodigies, whether in the organic or the inorganic world, to an infraction of the laws by which natural phenomena are regulated, by the intermediate interposition *ad hoc* of a supreme will for temporary motives inscrutable to man, in which all that the man of science was called upon to do was to establish their authenticity, and detail their abnormities. This, however, was considered by D'Alembert as sufficient to constitute Teratology as one of the great branches of Natural History taken in its most extended sense; for in his once celebrated "Système Figuré des Connaissance Humaines," *Histoire Naturelle* has three great branches—*Uniformité de la Nature*, or the study of the laws which govern the organic or inorganic world, terrestrial and celestial; *Ecarts de la Nature*, the science of prodigies and monsters; and *Usages de la Nature*, or arts and manufactures. Jeremy Bentham, in his "Essay on Nomenclature and Classification," of which I published a French edition now nearly half a century since, strongly criticised such a classification, "by which a middle-sized man is placed in one niche, a tall man and a short man together in another."* Mr. Galton however, in his recently published interesting researches on Hereditary Genius, shows us, after Quetelet, that even in this respect the laws which govern the deviations from the average height of man, both above and below that average, are uniform under similar conditions, and may well be studied together.

We may not, indeed, with D'Alembert, combine the history of animal and vegetable monstrosities with that of mineral monsters and celestial prodigies (whatever these may be); but the course which Biology has taken in the last few years has shown the necessity of accurately investigating in each branch all observed departures from what appears to be the ordinary course, before the real laws of that ordinary course can be ascertained. A work, therefore, in which these observed aberrations are carefully collected, tested, and methodised, cannot fail to be of great use to the physiologist, and such a work with regard to plants, the want of which, brought down to the present state of the science, I alluded to in my Address of 1864, has now been provided for us by Dr. Masters, in his "Vegetable Teratology,"—a work which we should especially like to see deposited in local libraries at home and abroad, to which observers resident in the country could have ready access. Monstrosities or deviations from the ordinary forms in plants are comparatively rare and evanescent; they can be best observed in their fresh state, and often require watching in the course of their development. Country residents have the best means of doing so, and to them it is very important to have a systematic work at hand by which they can ascertain whether the aberration they have met with is one well known or of frequent occurrence, or whether it presents any new feature, adding another item to our store of data, and therefore requiring closer observation and accurate record.

* Essay on Nomenclature and Classification, or *Chresstomathia*, part ii. 1817, p. 157, French Edition, 1823, p. 48.

In making use, however, of Teratology in explanation of structure and affinities, great care is required. It is not every one who can handle these phenomena with the tact of a Darwin. In the course of my systematic labours I have met with several instances where teratologists have been led into conclusions which have proved to be far wide of the truth, owing to their having confined themselves to teratology to the neglect of homology and organogeny. This importance of teratological facts to the physiologist who is able duly to appreciate their bearing, and the discredit cast on their study owing to their misuse in hasty and incautious speculations, are alluded to in Dr. Masters's Introduction. But beyond some explanations of causes suggested by the bringing together a series of facts showing a physiological connection with each other, and with more normal formations, he enters little into the various questions the solution of which has been more or less attempted by the aid of teratology. These questions, indeed, could not have been discussed without fully working out on each occasion normal organogeny, development, and homology, and thus leading him far beyond the object of the present work, which was to present to the future physiologist such a digested record of facts as should best show their relative bearing to each other, to normal conditions, and to any observed causes of disturbance. This object appears to have been well fulfilled, and the method adopted by the author probably the best suited to the purpose. A classification, founded upon the nature of the causes inducing the several changes, might, indeed, as he observes, have been theoretically the best, but is wholly impracticable until these causes shall have been satisfactorily ascertained. For the inquiry into these causes this teratological digest supplies a record of one class of facts, a necessary one, but only one of many classes on which it must be founded.

G. BENTHAM

SCIENTIFIC SERIALS

Journal of the Chemical Society, April 1870. This number contains a "Note on some Reactions of Alcohols," by Mr. E. T. Chapman. The author finds that on distilling with caustic soda a mixture of the rotating and non-rotating amylic alcohols to dryness, the distillate contains a larger proportion of the rotating alcohol than the original liquid; and, on adding water to the residue of sodic amylate and distilling the alcohol which passes over with the water is almost free from the rotating variety. A repetition of the process renders it quite pure. He also finds that repeated treatment of the rotating alcohol by caustic soda converts it into the non-rotating. On treating amylic alcohol to which about 2½ per cent. of water was added with a quantity of sodium just sufficient to decompose the water, and distilling, water first passed over, followed by amylic alcohol; sodic amylate almost free from caustic soda remaining in the retort; showing that the sodium replaces the hydrogen of the alcohol in preference to that of the water. Again, on distilling a solution of caustic soda in amylic alcohol, water passed over with the alcohol, the residue being sodic amylate.—"Note on the Organic Matter contained in Air," by Mr. E. T. Chapman. Several methods were tried for collecting the organic matter from the air before estimating its quantity. Passing the air through water in a Liebig's potash apparatus, or even in a tube with twenty-five bulbs, did not fix the whole of the organic matters. Cotton wool and gun-cotton failed on account of their invariably containing nitrogenous bodies, which vitiated the results; the condensation of steam in the air and washing with fine spray were better, but not satisfactory. Filtering the air through asbestos paper succeeded very well, but the asbestos was difficult to manage. The process finally adopted was to pass 100 litres of air through a quantity of finely powdered and moistened pumice stone, placed on a piece of wire gauze, fixed on the wide end of a funnel; distilling the pumice with dilute potassic hydrate and potassic permanganate, and determining the quantity of ammonia in the distillate by Nessler's test. In crowded rooms and near an untrapped sink, the air was found to contain organic bases as well as ammonia. 100 litres of air from crowded rooms contained quantities of nitrogenous substances, producing from 0·02 to 0·35 milligrammes of ammonia.—Then follows a lecture by Dr. Gladstone on "Refraction equivalents," which has already been noticed in these columns. The number concludes with a long paper by Dr. Thudichum on "Kryptophanic acid, the normal free acid of Human Urine." From the analysis of the salts it appears to be a dibasic acid of the formula $C_5 . H_9 \ N \ O_5$ or a tetrabasic acid containing $C_{10} H_{18} N_2 O_{10}$.

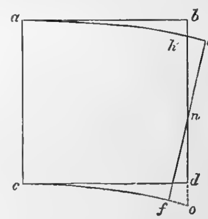
The May number of the *Journal of the Chemical Society* opens with an important paper by Mr. W. H. Perkin on "Artificial Alizarin." He first gives a sketch of the notions entertained by chemists as to the composition and relations of this important colouring matter prior to the investigations of Messrs. Graebe and Liebermann. These chemists showed that by treating alizarin obtained from madder with powdered zinc, a hydrocarbon was produced of the composition $C_{14} H_{10}$ and possessing all the properties of the anthracene of coal tar. By oxidising anthracene it is converted into anthraquinone $C_{14} H_8 O_2$; by the action of bromine dibromanthraquinone $C_{14} H_6 Br_2 O_2$ is produced, and by subsequent treatment with potassic hydrate at a high temperature, an alkaline solution of alizarin $C_{14} H_8 O_4$ is obtained—being the first instance of the artificial formation of a natural colouring matter. Mr. Perkin, in England, and Messrs. Caro, Graebe, and Liebermann, in Germany, have succeeded in obtaining the alizarin without the use of bromine. This may be effected by treating the anthraquinone with strong sulphuric acid, when disulphanthraquinonic acid $C_{14} H_6 O_2 (HSO_3)_2$ is formed, and this, when digested with potassic hydrate at 180°, gives rise to potassic sulphate and the potash compound of alizarin. The alizarin prepared from anthracene is identical with that extracted from madder. It has the same appearance, behaves in the same manner with reagents, produces the same effects in the dye bath, and exhibits the same absorption bands when examined spectroscopically. Two patterns dyed with artificial alizarin accompany the paper.—The second paper is by Mr. John Hunter, and contains some "Analyses of Deep Sea Water, and of some Ooze from the bottom of the Atlantic," collected during the expedition of H.M.S. *Porcupine*.—We then have a paper by Dr. Gladstone, on the "Refraction Equivalents of Aromatic Hydrocarbons and their Derivatives," being a continuation of the subject of the lecture reported in the previous number. Messrs. T. Bolas and C. E. Groves have experimented on the preparation of bromopicrin. They give exact directions for the preparation of this substance by acting on picric acid with bromide of lime, a compound analogous to bleaching powder. Bromopicrin has a very high specific gravity, 2·811 at 12·5°C. The authors announce that they have obtained the carbonic bromide CBr_4 by acting on bromopicrin with powerful brominating agents.—The concluding paper is by Prof. How, on an "Acidified Water from the Coal-field of Stellarton, Nova Scotia." This water was found to be distinctly acid, in consequence of its containing a considerable quantity of free sulphuric acid, probably produced from the iron pyrites present in the coal strata.

SOCIETIES AND ACADEMIES

London

Royal Society, May 19.—"On the Cause and Theoretic Value of the Resistance of Flexure in Beams." By W. H. Barlow, F.R.S.

The author refers to his previous papers, read in 1855 and 1857, wherein he described experiments showing the existence of an element of strength in beams, which varied with the degree of flexure, and acts, in addition to the resistance of tension and compression of the longitudinal fibres. It was pointed out that the ratio of the actual strength of solid rectangular beams to the strength, as computed by the theory of Leibnitz is, in cast iron, as about $2\frac{1}{4}$ to 1; in wrought iron as $1\frac{3}{5}$ and $1\frac{3}{4}$ to 1; and in steel, as $1\frac{3}{5}$ and $1\frac{2}{5}$ to 1. The theory of Leibnitz assumes a beam to be composed of longitudinal fibres only, contiguous, but unconnected, and exercising no mutual lateral action. But it is remarked that a beam so constituted would possess no power to resist transverse stress, and would only have the properties of a rope. Cast iron and steel contain no actual fibre, and wrought iron (although some qualities are fibrous) is able to resist strain nearly equally in any direction. The idea of fibre is convenient as facilitating investigation; but the word fibre, as applied to a homogeneous elastic solid, must not be understood as meaning filaments of the material. In effect it represents lines of direction, in which the action of forces can be ascertained and measured, for in torsion-shearing and "*angular deformation*" the fibres are treated by former writers as being at the angle of 45°, because it has been shown that the diagonal resistances have their greatest manifestation at that angle. Elastic solids being admitted to possess powers of resistance in the direction of the diagonals, attention is called to omission of the effect of resistance in the theory of beams. The author then states, as the result of his investigation, that compression and extension of the diagonal fibres constitute an element of strength equal to that of the longitudinal fibres, and that *flexure* is the consequence of the relative extensions and compressions in the direct and diagonal fibres, arising out of the amount, position, and direction of applied forces. Pursuing the subject, it is shown that certain normal relations subsist between the strains of direct fibres and their relative diagonals, evenly distributed strain being that in which the strain in the direct fibres is accompanied by half the amount of strain in the relative diagonal fibres. Any disturbance of this relation indicates the presence of another force. Thus tensile forces applied at *right angles* to compressive forces of equal amount, produce no strain in the diagonals. But if forces applied at right angles to each other are both tensile, or both compressive, the strain in the diagonal is as great as that in the direct fibres. It is also pointed out that in a given fibre *a*, *b*, *c*, the point may be moved with regard to *a* and *c*, thus producing plus and minus strains in the same fibre. Treating a solid as being made up of a series of laminæ, and showing that every change of figure can be represented by the variation in length of the diagonals, taken in connection with those of the direct fibres, the author proceeds to trace the effects of the application of tensile and compressive forces acting longitudinally on either side of the neutral plane, and shows that curvature is the result of the relation between the strains in direct fibres and those in the diagonals. The operation of a single tensile force applied along one side of the plate and a transverse stress are likewise traced out, and the conditions of "*elastic equilibrium*" referred to. The amount of resistance offered by the diagonal fibres is shown as follows:—



a, *b*, *c*, *d* represents a portion of a beam strained by transverse forces into the circular curve *a*, *e*. Two resistances arise. 1. That due to the extension and compression of the longitudinal fibres produced by the rotation of *b*, *d* about the neutral axis, which is the resistance considered in the theory of Leibnitz. 2. That due to the extension and compression of the diagonal fibres, caused by the deformation of the square *a*, *b*, *c*, *d* into the figure *a*, *h*, *o*, *c*, which is the resistance of flexure. It is then shown that in a solid rectangular beam, the second resistance is equal to the first, and that both resistances act independently, and consequently that the true theoretic resistance of a solid rectangular beam is exactly twice that arrived at by the theory of Leibnitz. The strength so computed is in general accordance with the results of experiments in cast iron, wrought iron, steel, and other materials, the maximum strength being found in cast iron, which is one-eighth above, and the minimum in glass, which is one-fourth below the calculated strength. The author considers this treatment of the subject as arising necessarily out of Dr. Hook's law "ut tensio sic vis," and that it is in effect completing the application of those principles which are only partially applied by Leibnitz. The paper concludes with some practical illustrations (accompanied by photographs) of the effect of diagonal action. The appendix contains the results of experiments on the tensile, compressive, and transverse resistances of steel.

"On some Elementary Principles in Animal Mechanics.—No. IV. On the difference between a Hand and a Foot, as shown by their Flexor Tendons." By the Rev. Samuel Haughton, M.D. Dubl., D.C.L. Oxon, Fellow of Trinity College, Dublin.

The fore feet of vertebrate animals are often used merely as organs of locomotion, like the hind feet; and in the higher mammals they are more or less "cephalised," or appropriated as hands to the use of the brain. The proper use of a hand when thus specialised in its action, is to grasp objects; while the proper use of a foot is to propel the animal forward by the intervention of the ground. In the case of the hand, the flexor muscles of the fore-arm act upon the finger tendons, in a direction from the muscles towards the tendons, which latter undergo friction at the wrist and other joints of the hand, the force being applied by the muscles to the tendon above the wrist, and the resistance being applied at the extremities of the tendons below the wrist by the object grasped by the hand. From the principle of "Least Action in Nature" we are entitled to assume the strength of each portion of a tendon to be proportional to the force it is required to transmit; and since, in a proper hand, these forces are continually diminished by friction, as we proceed from the muscle to the fingers, we should expect the strength of the tendon above the wrist to be greater than the united strengths of all the finger-tendons. Conversely, in a proper foot, the force is applied by the ground to the extremities of the tendons of the toes, and transmitted to the flexor muscles of the leg, by means of the tendons of the inner ankle, which undergo friction in passing round that and the other joints of the foot. In this case, therefore, we should expect the united strengths of the flexor tendons of the toes to exceed the strength of the flexor tendons above the heel. In the case of the hand, friction acts against the muscles; in the case of the foot, friction aids the muscles. I have measured the relative strengths of the deep flexor tendons of the hand above and below the wrist in several animals, and also the relative strengths of the long flexor tendons of the foot above and below the ankle, in the following manner:—I weighed certain lengths of the tendons above the wrist and ankle, and compared these weights with the weights of equal lengths of the flexor tendons of the fingers or toes, assuming that the weights of equal lengths are proportional to their cross sections, and these again proportional to the strengths of the tendons at the place of section. The difference between the weights above and below the joint represents the sum of all the frictions experienced by the tendons between the two points of section. Tables are given showing the results of measurements, *e.g.*, in the case of the Pyrenean Mastiff the amount of friction is 65·4 per cent., while in the Boomer Kangaroo it is *nil*. The foregoing animals all realise the typical idea of a true foot, with a variable amount of friction at the ankle-joint; this friction disappearing altogether in the Boomer Kangaroo, whose method of progression realises absolute mechanical perfection, as no force whatever is consumed by the friction of the flexor tendons at the heel. The only animals whose feet deviated from the typical foot were three, viz., the Alligator, common Porcupine, and Phalanger. In these animals the foot has the mechanical action of a hand, or grasping organ; and the flexor tendons above the ankle exceeded those below the ankle by the following amounts:—Alligator, 11·5 per cent.; common Porcupine, 20·0; Phalanger, 29·2. In the case of the flexor tendons of the hand results were obtained varying from 71·0 in the case of the Common Porcupine, to *nil* in the case of the Goat. It will be observed that the fore foot of the goat, regarded simply as an organ of locomotion, attains a perfection comparable with that of the hind foot of the kangaroo, no force being lost by friction at the wrist-joint. The only animal in which I found a departure from the typical hand was the Llama, in which the flexor tendons of the fingers exceed the flexor tendon above the wrist by 14·4 per cent. The bearing of the foregoing results on the habits of locomotion of the several animals will suggest themselves at once to naturalists who have carefully studied those habits. I shall merely add that the subject admits of being carried into the details of the separate or combined actions of the several fingers and toes, and that the habits of various kinds of monkeys in the use of certain combinations of fingers or toes may be explained satisfactorily by the minute study of the arrangement and several strengths of the various flexor tendons distributed to the fingers or toes.

PARIS

Academy of Sciences, May 23.—M. Jordan communicated a theorem on doubly periodical functions.—A note by M. L. Cailletet on the compressibility of gas at high pressures, was communicated by M. H. Sainte-Claire Deville.—M. Chapelas presented a note on the aurora borealis of the 20th May, which was observed to move from west to east, and was followed by great atmospheric disturbances coming from the south-west.—M. E. Lagout described a cheap equatorial sundial which he has invented for the purpose of regulating timepieces. It costs from 8 to 12 francs.—M. A. Trécul presented a note on the hailstones which fell at Paris during the storm of the 22nd May. These were pear-shaped, and very large, some measuring more than three-quarters of an inch in length. One of them showed at its larger end the form of an obtuse-angled rhombus.—A note on the clouds, fogs, and rains with sand, observed in Italy in 1869, by M. Zantedeschi, was read.—Several chemical papers were communicated, namely:—A memoir on the action of water upon iron, and of hydrogen upon oxide of iron, by M. H. Sainte-Claire Deville. A report by M. Chevreul on a memoir by M. Vétillart on the vegetable fibres employed in manufactures, describing the distinctive characters of the principal textile materials as evinced by microscopic observation and by treatment with iodine and sulphuric acid. A note by M. Schützenberger on the compounds of protochloride of platinum with oxide of carbon; one by M. M. Prudhomme on the action of acetylene upon acetohypochlorous anhydride (acetate of chlorine); and one by the same author, on the action of sulphuric anhydride upon protochloride and sesquichloride of carbon, all communicated by M. H. Sainte-Claire Deville.—Observations on the constitution of the flame of the fish-tail gas-burner, by M. A. Baudrimont. The author found that the obscure part of the flame possesses heat sufficient to fuse a platinum wire.—A note by M. A. Vezian, on the system of mineral veins of the Hundsrück, was read; and an extract from a letter by M. de Botella, noticing two recent cases of elevation of land in Spain. Upon the latter M. Elie de Beaumont made some remarks.—M. Cl. Bernard presented a contribution to the knowledge of the minute structure of the mammary gland, by MM. G. Giannuzzi and E. Falaschi. M. d'Abbadie suggested the desirableness of a decimal division of the circle and of time; and General Morin presented a note on some earthenware stoves, manufactured by Müller and Co., of Ivry, which, as he stated, utilise no less than 93 per cent. of the heat developed by the coke consumed in them. Several other papers and communications were read of which the titles only are given.

May 30.—A paper by M. E. Combescène on some differential formulæ was presented by M. Hermite; and a note on a formula of analysis, by M. F. Lucas, was communicated by M. Liouville. General Morin communicated a memoir by MM. C. Martins and G. Chancel on the physical phenomena which accompany the rupture of hollow projectiles of various calibres by the congelation of water contained in them. The numbers obtained by the authors are about one half those obtained by General Morin from the formulæ given by him in his lectures on practical mechanics. General Morin, M. Dumas, and M. Elie de Beaumont made some remarks upon this communication.—M. Jamin presented a note by MM. A. Cornu and E. Mercadier, on melodic and harmonic intervals, in reply to a paper by M. Guéroult, read on May 9.—M. Jamin also communicated two notes by M. Trève on electric currents. In one of these the author cited some further observations in support of his assertion that two currents cannot circulate in opposite directions in the same wire or in the same Geissler's tube; in the second he indicated a method of explaining the course of the currents in telegraphy when terrestrial communications are employed without a return wire. He maintained that the soil is to be regarded as a common reservoir rather than as a conductor.—A note by M. J. Mario on the phenomena of electrostatic induction was read. From his experiments he proposed a theory of terrestrial currents, according to which the sun would be a source of positive electricity acting by induction upon the earth.—A note by M. Neyreneuf, on the theory of electrical condensers, was also read.—The following papers on chemical subjects were read:—A note by M. Cloëz, claiming priority in the discovery of the cyanic and cyanuric æthers, presented by M. Cahours.—A note by MM. Gal and Gay-Lussac, also presented by M. Cahours, on some compounds homologous with tartaric and malic acids. These compounds were adipomalic, adipotartaric, suberomalic, and suberotartaric acids; they are obtained by the action of bromine upon adipic and suberic acids.—A note on the action of hydrochloric acid upon osseine, including researches upon determination of the quantity of osseine in fossil bones, by M. Scheurer Kestner, communicated by M. Balard. The author stated that the solubility of a portion of the osseine in bones is independent of the action of hydrochloric acid, which may be reduced to almost nothing by sufficient dilution. He replied to some remarks of M. Elie de Beaumont on his former paper on this subject.—A note, by M. Sacc, on the preparation of pyrotartaric acid. The process proposed by the author consists in disolving anhydrous tartaric acid in commercial acetic acid, and heating the mixture in a retort until it becomes syrupous; in a day or two the vessel is filled with acicular crystals.—A memoir was read on the organisation of silicified branches probably belonging to a *Sphenophyllum*, by M. B. Renault. The author described the structure of a stem, which he identifies with *Sphenophyllum* (naming the species *S. Charmassii*), and from the characters displayed by which he is led to remove *Sphenophyllum* from the Equisetaceæ.—M. Blanchard presented a memoir by M. Lacaze Duthiers containing his researches upon the evolution of *Molgula tubulosa.* The author stated that the larva of this species, instead of the tadpole-like form supposed to be common to the larvæ of the Ascidia, is an amœboid body which, as it were, flows out of the ruptured egg.—M. A. Dumèril presented a note, by M. G. Pouchet, on some monstrous gold fish (*Cyprinus auratus*) from China. This note related to the well-known doubling of the tail in these fish, which, according to the author, always occurs below the extremity of the vertebral column.—M. de Quatrefages presented a note, by M. Bordone, on the organisms which are developed in the silkworms attacked by the disease called *Morts flats.* M. Dumas made some remarks upon this paper.—M. Decaisne communicated a note, by M. J. E. Planchon, on the Phthiriosis of the vine known to the ancients, and on the Coccidæ of the vine of modern times. The cause of the vine-disease known to the Greeks as Phthiriosis is said by M. Koressios to be the *Phylloxera;* the author stated that it was a coccid, but not, as supposed by Walckenaer, the *Coccus Vitis.* (Linn.) He identified it with *Dactylopius longispinus*, of Targioni Tozzetti.—M. A Dumèril presented a note by M. E. Moreau, on the cranial region of *Amphioxus*, forming a continuation of his paper on the structure of the dorsal chord in that fish.—A note by M. N. Gréhant, on the rapidity of the absorption of oxide of carbon by the lungs, was commnuicated by M. Cl. Bernard. The author stated that the absorption of oxide of carbon into the blood commences immediately, and advances rapidly. The blood of a dog breathing air containing one-tenth of oxide of carbon, furnished a gaseous mixture containing 4·28 per cent. of oxide of carbon, in less than 25 seconds, and 18·41 per cent. in less than $1\frac{1}{2}$ minute.—M. C. Robin presented a note by M. J. Chéron, on the state of muscular contractibility, judged comparatively by means of continuous currents, and of currents of induction, in a certain number of paralyses.—M. C. Sainte-Claire Deville presented the first volume of the "Bulletin of the Meteorological Observatory of Montsouris," and made some remarks upon its contents.—Numerous other papers and memoirs were communicated, of which we have only the titles.

BERLIN

German Chemical Society, May 23.—M. Ador has obtained the radical of phthalic acid by treating its chloride with silver. Three molecules thus unite into one. The new body yields three different acids by oxidation, the last of which is phthalic acid.—A. Baeyer, in his own and in M. Emmerling's name, reported on the transformation of isatine into indigo. As isatine, when treated with nascent hydrogen, unites with it and forms indol, a substance not capable of uniting with the reduced substance was sought for, and discovered in phosphorus, the solvent employed being chloride of acetyle or of phosphorus. Real indigo-blue and indigo-red were thus produced. The latter stands in the same relation to the blue as purpurine does to alizarine. To complete the long hoped-for discovery of producing artificial indigo, all that remains to be done is now to transform indol into isatine.—Prof. Cannizzaro, of Palermo, sent in a paper on isomeric cyanuric ethers. Solid chloride of cyanogen acting on benzylic alcohol produces an ether isomeric with one formerly described, and belonging to the series lately investigated by Hofmann.—Messrs. Gomp-Besanez and Grinva have produced artificially the essential oil of rue by distilling together caprate of sodium $C_{10}H_{19}NaO_2$, and acetate of sodium. The acetonic nature and the formula $C_{11}H_{22}O$ (hitherto doubtful) of the oil are thereby fully established.—C. Rammelsberg, in a paper on meteorites, remarked on the absence of alkalis in these celestial rocks. The "Shalkah" stone found in India has lately been analysed, and consists of 22 per cent. of olivine and 88 per cent. of bronzit. He found that sulphuric acid only attacks the former mineral and leaves the latter untouched.—Messrs. Naumann and Vogt report on what Wurtz considered as a combination of chloride of cyanogen with hydrocyanic acid, but which according to them is a mixture.—A. Claus has studied the action of bromine on dichlorhydrine, and that of chloride of sulphur on aniline. The latter reaction has not as yet produced pure substances.—L. Henry by treating with nitric acid, glycol, lactic, and malic acids, has replaced the alcoholic group O H by the group NO_2.—A. W. Hofmann reported on the danger of preparing chloride of cyanogen by the action of chlorine on cyanide of mercury. Sometimes explosions take place during this preparation, particularly at the end of it, when the salt remaining behind and acted upon is a double salt of the chloride and the cyanide of mercury.—Messrs. Baeyer and Martins recommended the action of chlorine on hydrocyanic acid, and that of chloride of lime on cyanide of potassium for producing chloride of cyanogen.

THE SCIENTIFIC EDUCATION OF WOMEN

THE feature which will probably most clearly mark the year 1869 in the view of the future historian of Education, will be the definite recognition of the rights of woman to all the advantages of education accorded to men. The advance of public opinion within the last few years on all subjects relating to the legal, social, and educational position of woman, has indeed been so rapid, that the man whose words were only quite recently listened to by his friends with a condescending smile of pity, is now scarcely in advance of his times. As it is generally believed that the movement has yet far from reached its full development, and the course in which it has been so far directed having been in the main sound and excellent, we would still wish to suggest to its promoters whether the curriculum of subjects taught under the auspices of the various associations may not be somewhat widened by a more liberal infusion of the scientific element. The ability of women to appreciate instruction by the highest teachers of Natural Science has as yet hardly been tested. The high position occupied by a few women like Miss Martineau and Mrs. Somerville as writers on Political and Natural Science cannot be taken to prove the capacity of the whole sex; but we think that so far as opportunity has yet been offered, the evidence is entirely favourable. The programmes of the Lectures to Women on Physiography, Physics, and Botany, recently delivered at the South Kensington Museum by Professors Huxley, Guthrie, and Oliver, show at least no want of confidence in the capacity of their pupils. The first of these courses had already been given substantially to a mixed class of boys and girls at the London Institution, and in the results of the examination of that class, the girls had decidedly the advantage over the boys. In most of the large towns of Great Britain courses of lectures to ladies have now been delivered during the last two or three years by eminent professors of the various branches of literature; in many of these rigorous examinations have been held at the close of the courses; and where this has been done, there is but one expression of opinion as to the quality of the work executed. At London, Edinburgh, Manchester, Liverpool; in English literature, mathematics, experimental physics, mental philosophy, the testimony is uniform, that not only can women compete with men in the qualities essential for severe and successful study, but that in many respects their average attainments are higher than among the working members of a University. A careful examination of the reports of the various educational associations convinces us that this statement is decidedly within the mark. Among so many testimonies to the same effect, it seems almost invidious to pick out one; but we cannot forbear quoting from Professor Fraser's report of his class of logic and mental philosophy at Edinburgh:—"Sixty-five students enrolled. Forty-eight of these shared more or less in the examinations and essays of the class. I found, as the session advanced, that I had at the outset underrated the mental power and persistency of as able and zealous a set of students as I have ever had the good fortune to conduct. . . In the examination the average of marks gained was about 55 per cent.; one-twelfth of the class gained more than 80 per cent. of the marks, and only one had less than 25 per cent."

The Edinburgh Association stands out from most of its kindred societies in being formed on a decidedly more academical basis. The courses are longer, averaging about forty lectures each, and, consequently, deeper and more thorough: the teachers are all university professors, and the aim of the Association is, as it were, to form a distinct Faculty of the University. So far as we can judge, the success of the Association has justified the views of its founders. Many advantages no doubt result from immediate connection with a great centre of learning like the University of Edinburgh, a connection which has hitherto been denied to female education. We are inclined to think that the "College for Women" may have made a mistake in establishing itself in a locality "midway between London and Cambridge." The College will not share in the life of the University; the Cambridge professors will not feel the Hitchin College a portion of their own system, unless the College is locally associated with the University.

We have already alluded to the comparative absence of Natural Science from the programmes of the Ladies' Educational Associations; this is not so strikingly the case as it was last year. The London Association is making arrangements for some scientific classes next session; at Edinburgh Professor Balfour is trying the experiment of a class of botany; classes for zoology and geology are included in the Manchester curriculum for 1870-71; as well as one on logic by Professor Jevons; Natural Science has a place both in the entrance examination for the Hitchin College and in the College course, though it has not yet been taught; while chemical classes have already been conducted in several localities by Professors Williamson, Roscoe, and others, with marked success. We notice with great pleasure the movement at Cambridge for the instruction of women to which we have referred elsewhere. Here a wide field is opening for the future, and one which it will surprise us if women do not make especially their own. In the training of boys we have recently awoke to the discovery that a complete education implies something more than an intimate acquaintance with two dead languages. There is no danger that we shall ever underrate the value of a critical acquaintance with Latin and Greek, as requiring a mental training which no other studies can give; but while a classical education imparts the highest culture possible to the intuitive faculties, it scarcely brings into play the powers of observation. Now, it is in these very powers of perception, as distinct from conception, which the Natural Sciences cultivate, that woman has naturally the advantage over man; and we may therefore *a priori* conclude that their study will be specially within the range of her powers. Another consideration is also worthy of notice by those who are looking for "new careers for women." At a time when we are beginning to recognise the importance of a scientific training as an essential portion of a liberal education, we find that our teaching powers fail us. The number of really competent teachers of science has by no means kept pace with the extension of a desire for instruction; the leading men in every branch are overwhelmed with work; and the younger men to whom they can with confidence entrust a portion of their labours are by no means sufficiently numerous. It is thus not women only, but men, the whole human race, that is stunted in its intellectual development at a time when its growth should be the most rapid, by the practical restriction to one half of the race only, of the means of acquiring the ability to help in this development.

We must next touch upon a subject of great delicacy; we refer to the instruction of women in medicine and surgery. There is an important distinction between this and all other departments of science. While it is competent to any one to teach chemistry, geology, or botany, and his success as a teacher will depend on his competency, the teachers and practisers of medicine and surgery form a guild, a professional trades' union, protected and licensed by the Government. It is in the nature of guilds and monopolies to be exclusive; and when we find that the medical profession is united almost as one man (with a few honourable exceptions) to resist the admission of women into its ranks, it is only what might with confidence have been predicted. The instinct of self-defence is a strong one; and if any evidence is required of the extent to which self-interest has entered into the causes of the opposition by the profession to the medical training of women, we need only refer to the "seven reasons against the admission of ladies to the profession" given in the *British Medical Journal* for May 7th. Into the abstract question of the utility of monopolies we need not enter; those who are excluded from their benefits are perfectly justified in using every legitimate effort to overthrow them, and in claiming the assistance of those who believe in the universal adaptation of the principles of free trade. Seldom have greater persistence and self-denial been shown than by those few women who have laboured long and hard in this country, America, and France, in attempting to open to their sisters the doors of the medical profession. Careless of cruel misrepresentation, of public slander, of private persecution, they have held nobly on their course, and their services to mankind will one day be recognised.

Few have yet realised the enormous gain that will accrue to society from the scientific education of our women. If, as we are constantly being told, the "sphere of woman" is at home, what duty can be more clearly incumbent upon us than that of giving her the opportunity of acquiring a knowledge of the laws which ought to guide her in the rule of her house? Every woman on whom the management of a household devolves may profit by such knowledge. If the laws of health were better known, how much illness and sorrow might be averted! What insight would a knowledge of chemistry afford into the wholesomeness or unwholesomeness of different articles of food! What added zest would be given to a country walk with the children, or a month by the seaside, if the mother were able to teach the little ones intelligently to observe and revere the laws of Nature! Above all, what untold sufferings, what wasted lives, are the penalty we have paid for the prudish ignorance of the physiology of their bodily frame in which we have kept our daughters! These considerations have had far too little place with us at present.

We trust that a new era is dawning upon us; may the higher education of women be pursued in the admirable spirit of the last report of the Edinburgh Ladies' Educational Association:—"So far as we can see, cultivation does for women what it does for men—intensifies every moral attribute in proportion to the mental growth. Those who must go out into the world go out with a truer courage, founded upon a nobler estimate of work; those whose duties lie within the circle of home find them invested with a new and vivid significance from the higher elevation, and consequently larger views, of their own minds; and, finally, as 'woman is not undeveloped man,' we believe that womanhood can only be made more truly womanly, as manhood is made more truly manly, by the utmost use of the possibilities of high cultivation."

NATURAL HISTORY COLLECTIONS

ALLOW me to give in my adhesion to the "platform" established by the signers of the Memorial concerning the Natural History Collections, reprinted in your last number, and at the same time to request you to reprint a second Memorial on the same subject, presented in 1866 to the then Chancellor of the Exchequer. You will observe that this Memorial has likewise been signed by many distinguished men of science.

P. L. SCLATER

Copy of a Memorial presented to the Right Hon. the Chancellor of the Exchequer

SIR,—It having been stated that the scientific men of the Metropolis are, as a body, entirely opposed to the removal of the Natural History Collections from their present situation in the British Museum, we, the undersigned Fellows of the Royal, Linnean, Geological, and Zoological Societies of London, beg leave to offer to you the following expression of our opinion upon the subject.

We are of opinion that it is of fundamental importance to the progress of the Natural Sciences in this country, that the administration of the National Natural History Collections should be separated from that of the Library and Art Collections, and placed under one officer, who should be immediately responsible to one of the Queen's Ministers.

We regard the exact locality of the National Museum of Natural History as a question of comparatively minor importance, provided that it be conveniently accessible and within the Metropolitan district.

FOSSIL MAMMALS IN NORTH AMERICA

The Extinct Mammalian Fauna of Dakota and Nebraska; together with a Synopsis of the Mammalian Remains of North America. By Dr. Leidy. With an Introduction on the Geology of the Tertiary Formations of Dakota and Nebraska; with a map. By Dr. Hayden. (Philadelphia, 1869.)

DR. LEIDY'S new work on the extinct mammalia and fauna of Dakota and Nebraska, to which is appended a Synopsis of the Mammalian Remains of North America, fills a wide gap in Palæontology. It occupies the whole of the seventh volume of the Journal of the Academy of Natural Sciences of Philadelphia, and is accompanied by a preface on the geology of the Tertiary Strata of Dakota and Nebraska, by Dr. Hayden. Altogether it forms the most important contribution to our knowledge of fossil mammals which has been made since Prof. Gaudry published his famous "Animaux Fossiles et Geologie de l'Attique." These two books, indeed, stand in close relation to one another, for in the one the chief interest centres in the Miocene fauna, which is the subject matter of the other. I propose to give an outline of Dr. Leidy's work, and to show the relation which the American Mammalia bore to those of Europe, from the Miocene down to the "Quaternary," or Post-glacial epoch.

At the close of the Cretaceous period, writes Prof. Hayden, the ocean which had "rolled uninterruptedly across the area now occupied by the Rocky Mountains" began to grow shallow, until at last a long barrier of land gradually rose above the waves, and separated the Atlantic from the Pacific. This elevatory movement culminated in the Rocky Mountain range in the United States, and probably has been going on from the Cretaceous period down to the present day. In the early Tertiary epoch enormous lakes occupied the basin of the Mississippi. The "great lignite basin," for instance, extends far southward, possibly even to California, westward far over the mountains to Utah, and possibly to the Pacific, and northward probably to the Arctic Sea, interrupted here and there by the upheaval of mountain ranges." The strata which testify to the former existence of this great lake, consist of layers of clay and sand, and numerous beds of lignite, varying in thickness from a few inches to twelve or fifteen feet. In its lower portion an oyster is the characteristic fossil, which by its stunted growth implies a change from salt to brackish water, while in the rest of the formation there are freshwater shells of the genera Melania and Corbicula. "The occurrence of immense fan palms, and many other plants now growing only in tropical climates, points directly to the conclusion that along the shores of this great lake there grew most luxuriant forests, equalled only by those now existing in Central America or Brazil." The date of this lignite formation is possibly Eocene, and certainly pre-Miocene. Some of these lakes continued to exist as late as the Pliocene epoch.

The "White River group" of rocks consists of white indurated clays, sandstones, and conglomerate marls and sands, upwards of a thousand feet thick, which occupy an area of at least 100,000 square miles on the Eastern flank of the Rocky Mountains. It is purely a fresh-water formation. In Nebraska it is eroded by pluvial and torrential action into quaint pinnacles and fantastic shapes of every sort, and into deep barren ravines that recall to mind Dr. Falconer's description of some parts of the Sevalik Hills. From the difficulty of traversing the 5,000 square miles which are cut up in this way the district is known to the Canadian voyagers as "Mauvaises Terres," and to the Indian hunters as the "Bad Grounds." It has furnished the larger portion of the Mammalia described by Dr. Leidy, and is unequivocally of Miocene Age. The Loup River Strata resting on the White River group, consist of sand and a few layers of limestone, and contain the remains of land and fresh water Testacea and Mammalia. In Nebraska, the sand is so incoherent that it forms a series of ever shifting dunes, which occupy an area of not less than 20,000 square miles. The remains of Elephant and Mastodon and others show that it belongs to the Pliocene, irrespective of the stratigraphical evidence. The Post-tertiary deposits are represented in the same region by a yellow siliceous marl, most fully developed along the Missouri River, and in the valley of the Plate. It is from three to five hundred feet in thickness, and contains well-known Post-glacial fossils.

In treating of the Mammalia yielded by these different formations, Dr. Leidy has followed the example of Prof. Agassiz in the needless multiplication of species. Naturalists fall into two classes, according to the ideas which they bring to bear on their work: the one fix their attention on the variability and points of resemblance manifested by suites of organic remains, and stretch the name of species as far as it will go; the other give specific value to minute differences of size and form, which, in a larger series of specimens, either recent or fossil, would be found valueless in classification. In this work Dr. Leidy has joined himself to the latter class, and has marked every small variation by a specific, and, in some cases, even a generic name, and by so doing has added, without any necessity, to the heavy burden of synonyms which scientific literature has to put up with. He believes that the American is a "peculiar fauna," and, that even if no difference between European and American fossils can be detected, their geographical separation is evidence that they belong to different species. For example, in the description of a new species, *Equus excelsus*, he admits that "it is not improbable that part of the specimens looked upon as fossils may be the remains of the Mustang, or recent wild horse of our western wilderness." Nevertheless, he holds to his own undefined specific name. This fault is carried to an extreme, in the case of the extinct family Anchitheriidæ. On the small foundation of one tooth, which, "in general proportions and construction," and "in size," is "nearly the same as the teeth of *Anchitherium Aurelianense*," a new genus, Anchippus, is based; while four milk molars, which "in form, mode of insertion, and general constitution and size, bear a near resemblance to those of the same species," constitute the basis of the second new genus Parahippus. This mode of treatment runs more or less throughout the work, and renders it of less value than might have been expected from the importance of the subject-matter. But, nevertheless, it is a mine of information to which Tertiary naturalists will resort for many long years to come.

I will now pass on to the consideration of the leading features of the Miocene fauna. On the borders of the ancient Miocene lake, from which the Mauvaises Terres were deposited, lived a most remarkable group of herbivores, all of which were, roughly speaking, less specialised than any now on the face of the earth. The Oreodon, a ruminant about the size of a large domestic sheep, was there in considerable abundance, and must have lived in herds, after the manner of the bison in the neighbouring region. It was an animal of a strangely composite kind; to the molar teeth of a ruminant it added the ulna and radius of a hog; it possessed a cranial and temporal region like that of the camel, and larmiers beneath the orbit as in the Cervidæ and the musk-sheep. Its canines were trilateral and worn like those of a pig, and its dental armature was complete all round. Three closely-allied forms, the Merychochœrus, Leptauchenia, and Agriochœrus, are associated with Oreodon, and form a group which, judged by existing forms of life, stands half-way between the pigs and the ruminants. It is an admirable instance of one of Prof. Huxley's "intercalary types." The camel or lama was represented by two allied forms, the Pœbrothere and Protomeryx, and the musk-deer by the Leptomeryx. The Artiodactyle division was present in very strong force. The Elotherium is allied to the hog, peccary, and hippopotamus. In a full complement of teeth it possessed a canine almost carnivorous in character. It was probably less omnivorous than any of the class now living. The Perchœrus, Leptochœrus, and Nanohyus, form members of the same class, together with the Hyopotamus and the Titanothere, which was possessed of a well-developed and separate ulna and radius. The remains of rhinoceros indicate one, and perhaps two forms, during the American Miocenes. The lowness of the crowns of their teeth, the large development of the incisors, and the absence of any trace of horn-basis on the skulls which have been preserved, imply that they belong to the hornless section Aceratherium, of Dr. Kaup, rather than to the true rhinoceros. Dr. Leidy has very rightly separated Hyracodon from the true rhinoceros, because it has the full complement of teeth in both jaws. The Anchithere represented the horse in this fauna; the Palœolagus the hare; and there were also squirrels, beavers, mice, and hedgehogs present.

There was also a corresponding development of the Carnivora. Two species of Amphicyon performed the function of the living foxes and wolves; the Hyænodon that of the hyæna; while the great Machairodus, and the allied form Dinictis, represented the lions, tigers, and other larger felines.

If this fauna be compared with that of the European Miocenes, several important differences and resemblances may be remarked. The whole group of antelopes, found in such numbers in the classic plains of Pikermi by M. Gaudré, and in central France, are absent. The giraffe also, and the family of the Cervidæ, and the horse, elephant, Mastodon and Hipparion of Europe, are equally absent. Other genera are common to both Europe and America. The *Elotherium Mortoni* of the Mauvaises Terres can scarcely be distinguished from the *E. Aymardi* of the Gironde. The *Anchitherium Bairdi* cannot be distinguished with certainty from the *A. Aurelianense* of France. The rhinoceros and Aceratherium of Eppelsheim and Pikermi find their analogues in the so-called *Rhinoceros occidentalis* and *R. meridianus* of America, while the Hyracodon recalls forcibly to mind the small rhinoceros from Sansan (*Aceratherium Sansanense*). The Lophiodon is also an American form. Of the Carnivores, the *Amphicyon vetus* is the equivalent of the *A. major* of De Blainville from Sansan, while the Hyænodon and the sabre-toothed Machairodus were the scourge of the Miocene herbivores in America as in Europe. The family of the Oreodontidæ, on the other hand, seem peculiar to America, as also the Titanothere and the small carnivore the Dinictis.

This distribution of life throws considerable light on the physical geography of the northern hemisphere during the Miocene period. The absence of the South American forms which were living at the time, the apes, the rodents, and the edentata, implies the presence of a barrier between North and South America, which prevented migration from the one to the other; and this barrier was most probably, as Prof. Huxley remarked in his last address to the Geological Society, an open sea. The forms of life common to Europe and North America imply a continuity of land between those now widely dissociated areas. Mr. Murray believes in the existence of a Miocene Atlantis, which has left the Sarghasso sea as a palpable monument of its existence in the mid-ocean. I should, however, be rather inclined to look for the continuity of land in the direction of Siberia, Behring's Straits, and, it may be, Greenland; and when the recent wonderful discoveries of temperate and sub-tropical vegetation in the now Arctic regions is taken into account, it appears to me extremely probable that the animals migrated from one area to the other by that pathway. But whether this be accepted or not, Prof. Heer has shown that during the Miocene times there was a vast extent of land, and a temperate climate in the now extremely high northern latitudes, which would imply conditions of life favourable for the migration of the Miocene animals. It is impossible to find out with any certainty the direction which the Miocene migration took, whether from America towards Europe and Asia, or *vice versa*. There is, however, one very significant fact to be observed, that the American Miocene fauna is less specialised than the European, or, in other words, that it is of an older type. It contains no true hyænas, nor deer, nor antelopes, nor any of the living genera which first appeared in the Miocenes of Europe. Possibly in point of time, or rather in homotaxy, it was older and more closely allied to the Eocene. The explanation which strongly suggests itself to my mind is that the migration set in from the old world, and that the above-named living genera sprang into being here, and are not found in the American Miocenes, because they had not time to reach that area. Thus the absence of certain extinct genera, such as mastodon and hipparion, may be accounted for. That eventually they found their way thither will be seen in the succeeding part of this essay relating to the Pliocene.

W. BOYD DAWKINS

NAUMANN ON THERMO-CHEMISTRY

Grundriss der Thermochemie. By S. Alex. Naumann. 8vo. pp. viii. and 150; price 3*s*. (Brunswick, 1869. London: Williams and Norgate.)

IT is not altogether without reason that modern chemists are accustomed to point, as a proof of their activity, to the amount of materials they have succeeded in accumulating. The fact, indeed, is sufficiently familiar to most students.

If any one will examine a popular chemical manual, he will find its pages occupied almost wholly with experimental results, connected by an imperfect and partial classification. Should he feel envious to know what laws have been acquired by the science, or how far it at present possesses a deductive form, the whole of the information he seeks is generally proffered in a few paragraphs. Nor can it be denied that, as a rule, the manuals have given a fair representation of the kind of chemistry that we are compelled to use for the purposes of teaching. But not only has this state of things been repeatedly predicted; the result has also been discerned. The most distinguished chemists have from time to time seen the fundamental identity that exists between their own science and that of physics, and have recommended the conjoint study of these subjects as likely to prove of the greatest advantage to each, until the apparent and illusive difference between them shall have vanished, and their separate efforts be blended in a single enterprise. In recent times, the special character formerly assigned to chemistry is advocated only by the few who are content with the prevailing style of research. Every one will, therefore appreciate the eager interest that has always been shown in any attempt to construct a firm and logical union between chemistry and physics. Such an union is now being accomplished by the science of Thermo-chemistry.

If we look back to the beginning of this century, we shall see how little reason we had to expect that the desired result would be brought about in such a manner. At that time, there were but few who did not regard heat as, in some way or other, a kind of matter, and not many who deemed its study of much importance. Lavoisier, it is true, touched the obscure topic with his restless fingers; but while we cannot withhold our respect from the inventor of the calorimeter, few will excuse the great opponent of phlogiston for his theory of caloric. Thénard, on the other hand, was the first to show, in his classification of the metals, the great importance to chemistry of the study of temperature. His principles and the fruit of his teaching can easily be traced in modern chemistry. But it was not in the study of pure thermotics that thermo-chemistry took its rise. That science could not furnish, what the weakness of the mind invariably demands, a conception on which to proceed. Heat might be a mode of motion. But motion of *what?* The passage in which Rumford announced his discovery is sublime in its simplicity and unsullied by any materialistic taint. The popular prejudice stripped that magnificent idea of its regal investiture, and clothed it in the garments of a corpuscular theory. Dalton's atomic doctrine, at first received with coldness, has long been almost universally accepted among chemists; but it is only, perhaps, within the last decennium (for Mayer and Joule must be omitted) that a few prominent physicists, among whom Naumann himself is to be enumerated, have given in their adhesion to Dalton's fundamental views, and constructed for themselves a new basis on which to work. Thus, then, has arisen the science of thermo-chemistry; and it is not, consequently, very surprising that it should teach us that heat is a kind of undulatory movement (*Bewegungsform*) of molecules or atoms. On the whole, we are inclined to regard the atomic constituent of the infant science as "accidental" (to borrow a term from mineralogy); in anything equal to a calculus, it will prove to be an intolerable hindrance to perspicuity, infecting the purely inductive part with a host of extraneous entanglements.

Professor Naumann is far too acute and experienced a reasoner not to perceive that it is precisely at this point that objections are most likely to be made. Accordingly he is careful to fortify his position by a well-digested chapter on the atomic theory, in which the usual arguments are advanced with much more than the usual thought and distinctness. It may aid the reader to form a judgment of how far his author has succeeded, if we notice one or two points in the discussion. Almost at the outset, we are warned that demands on the accuracy of a scientific theorist must not be severe or stern. "The essential value of a theory does not consist so much in its fundamental hypotheses, but in the connecting of known facts and enabling us to discover new relations." Further on there is sufficient confusion in the terms employed to mislead one into supposing that an element enters into combination with unaltered properties; whereas, of course, it must always gain or lose by that process. The existence of bodies having the same per-centage composition, but different reactions, is adduced to prove that the matter in them must be divided into discrete parts in each case. Does it not rather prove that matter has nothing whatever to do with chemical properties? Again, the passage beginning "If we now suppose the process of mechanical division to be carried on continuously, a limit must at length appear," &c., is as clear a case of *petitio principii* as we remember to have met with.

The work of Professor Naumann is intended as a sort of summary, in a form specially designed for the student, of what the science of thermo-chemistry has been able to achieve. The accomplished author, who has taken a most important practical share in the results he describes, has spared no pains to perfect his labour with such an end in view. We need hardly say that an effort, in itself so desirable and meritorious, is in its result both opportune and intelligible. We may as well, perhaps, point out that the chapters on Dissociation and kindred subjects have received, as was natural, the greatest amount of development.

The progress of biology has repeatedly been opposed by an obstacle which, under the name of "mind," it has scarcely known how to treat, but with respect to which it is just beginning to find its true position. In like manner, physical science, and chemistry particularly, has had to encounter a phenomenon which, under the name of "matter," has continually impressed upon it the heaviest and most severe of theoretical burdens. It will be strange, indeed, if biology should steal a march on physics.

E. J. MILLS

OUR BOOK SHELF

The Interior of the Earth. By H. P. Malet, F.L.C.S. 8vo, pp. 175. (London: Hodder and Stoughton, 1870.)

THIS is a very good example of a book which ought never to have been written. The author tells us in the introduction that, in approaching the most complicated problem of the condition of the interior of the earth, he has "culled from contemporary literature such extracts as fit" his subject, and that "his intention is to offer a new interpretation of observed phenomena." The "contemporary literature" which has afforded the materials for the "new interpretation" consists of Page's "Geological Manual," Phillip's "Vesuvius," and very many extracts from the current weekly and quarterly periodicals for the last year. With the exception of an allusion to M. Daubrée, obtained from an appendix to Professor Haughton's "Manual of Geology," the author shows no acquaintance with any of the French or German authorities who have worked so hard at his subject. He is, moreover, in ignorance of the labours of Sorby, and of the translation of Bischoff, published by the Cavendish Society. Had he read Lyell's "Principles" he would certainly not have been betrayed into writing such a strange book as the "Interior of the Earth."

We will give one sample of the quality of "the new interpretation." "Page tells us 'that the interstratified trap-tuffs, the basaltic outbursts, and the numerous faults and fissures testify to a period of intense igneous activity.' *We have a familiar example of this action in our hot-beds and our hay-ricks.*" Mr. Malet then proceeds to explain the earth's heat and volcanic phenomena by a like action on buried vegetable matter. To combat views such as these would be absurd. Their author has succeeded in gaining a place among geologists similar to that of the circle-squarer among mathematicians. Z.

Sitzungsberichte der Naturwissenschaftlichen Gesellschaft Isis in Dresden. (Jahrgang, 1869. Nos. 10—12.)

THIS part of the report of the Isis Natural History Society of Dresden contains as usual a great number of interesting notices in all departments of natural history, the most important being on botanical subjects, namely, the commencement of a prodromus of the Lichens of Saxony, Thuringia, and Northern Bohemia, by Dr. L. Rabenherst, and the conclusion of a synopsis of the Coniferæ, by M. Laessig. In the latter, diagnoses of the families and genera are given, and the general characters and geographical distribution of the species are indicated. In the continuation of a lecture on extinct mammalia, Dr. Günther noticed the following species:—*Canis familiaris fossilis*, *C. spelæus* (=*C. lupus*), *C. vulpes fossilis*, *Hyæna spelæa*, *Felis spelæa*, *F. antiqua*, Cuv., *F. minuta fossilis*, Wagn., *F. aphanista*, and *ogygia*, Kaup, and some species of *Mustela*. In a paper on recent explorations for rock-salt in Prussia, M. Otto noticed the occurrence of a vast bed of that mineral near Sperenberg, where a boring has been carried down 2,270 feet, of which 1,920 feet is through a salt bed. The boring has probably nearly reached the bottom of the deposit, as the material brought up now contains much anhydrite. Near Segeberg, in Holstein, a deposit of salt has been met with at a depth of 400 feet.

Milne-Edwards. Leçons sur la Physiologie et l'Anatomie comparée. Tome ix. 2me partie. (Paris: Masson et fils.)

WE gladly welcome another instalment of the long and great work, the "beautiful legacy," as Bernard has called it, of the venerable French naturalist. At a time when the "differentiation" of study is carried to such an extent that many physiologists know very little about other animals than frogs, rabbits, dogs, and men, and many zoologists have a very meagre acquaintance with the results of experimental physiology, such a work as this, which skilfully weaves together all the main facts of animal biology, is most wholesome reading. The present part continues the discussion of the Reproductive Organs of the Invertebrata, and contains two lectures on the Development of the Embryo. We trust the distinguished author may be spared still to preside over and finally to witness the conclusion of this great work.

M. F.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.]

The Apparent Size of the Moon

DR. INGLEBY is curious to know what Prof. Helmholtz would say on this vexed question. If Dr. Ingleby will turn to page 630 of the "Physiologische Optik," he will find that Prof. Helmholtz has anticipated his wishes. As others of your readers may be interested in seeing how the matter is treated by one who is *facile princeps* in this department, I subjoin a translation of the passage. If the curious experiment mentioned by Dr. Ingleby had referred only to the vertical diameter of the disc, it would have seemed to be another illustration of our inveterate tendency to ascribe an exaggerated value to vertical lines or angles, at or near the horizon. It is said that if ten men be required to fix off-hand on a star half way between the zenith and horizon, nine, at least, will choose one very much too low. If an exact square be cut out in paper and pinned against the wall opposite to the eye, the sides will appear longer than the top or bottom. If an equilateral triangle be placed in the same position, the angles at the base will appear larger than the angle at the vertex. If a line be drawn parallel to the bottom of a sheet of paper, and a second line, making with it an angle of 20° or 30°, any one attempting, without moving the paper, to draw a third line through the point of intersection, so as to make an angle with the second line equal to that which the second makes with the first, will make the second angle too large. (This experiment is guaranteed by Helmholtz.) After reading Helmholtz's theory, metaphysicians may be willing to allow that all these illusions are to be derived, after his example, from the clouds. As metaphysicians have, before now, contributed a good deal to the clouds, it is perhaps only fair that the clouds should contribute something to the metaphysicians.

W. T. RADFORD

"To this category also belongs the celebrated question why the moon appears larger when she is near the horizon than when she is high in the heavens, although, in point of fact, owing to atmospheric refraction, her vertical diameter ought in the former case to seem less than in the latter. Even Ptolemy and the Arabian astronomers were perfectly aware that the true reason why the moon appears larger when seen in the horizon, is that she then appears further off. The real question therefore is, why the sky should appear further from us at the horizon than it does at the zenith. Various causes have been assigned for this fact, and I am myself disposed to admit that there are several causes which combine to produce this effect, so that it may be difficult to say which of these causes predominates in any one case.

"First of all we must remember that there is no decisive reason why the starry firmament should appear to us to be a spherical surface. It certainly reveals to us objects (the stars) which are at an infinite distance; but hence we can only infer that it may assume the appearance of any such indeterminate surface as any motive whatever may lead us to ascribe to it. If we were floating in empty space, and could survey it in its whole extent at the same moment and in all directions, or if its movements were so rapid as to make a distinct impression on the senses, there might be more reason for assigning to it a spherical rather than any other kind of surface. In point of fact, however, its apparent form and apparent direction are constantly changing, according as the portion we happen to see is more or less enclosed by various terrestrial objects, and according as we fix our attention on a higher or a lower spot. We shall see further on that we are naturally disposed to regard it as a plane surface, at right angles to the line of sight, whenever both eyes are steadily fixed on one point.

"But with the canopy of cloud the case is entirely different. The clouds in general are so far from us that the criteria for judging of distance which binocular vision or the movement of our own bodies can supply are utterly useless. But the clouds are often disposed in parallel lines, they generally drift with a constant velocity and in the same direction; when near the horizon they appear like bars across the sky seen edgewise, and so lighted that it is easy to perceive they are bodies whose horizontal extension is foreshortened by perspective. All these indications serve to give us the impression that the true form of the canopy of cloud, at least in the zenith, is that of a very flat dome. On the horizon indeed these indications cease to serve us; there the clouds, like the mountains, appear to be evenly painted on a vertical or nearly vertical background, which gradually passes into the surface of the earth below, and into the firmament above. Now, since the senses supply no criteria by which we distinguish between the distance of the clouds and that of the sky, it seems only natural that we should ascribe to the one the ascertained form of the other, so far, at least, as we can separate them. This, I believe, is the way in which our conception of the sky, as a flat domelike vault, must originate, vague, variable, indefinite as that conception undoubtedly is.

"Moreover, the apparent increase in the size of the sun or the moon is never very striking or decided, except at those times when the air near the horizon is heavily charged with vapour, and when, as a necessary consequence, the heavenly bodies in question only shine with a very feeble light; we have then the very same effect with which we are perfectly familiar in the case of distant mountains. They appear more distant than they do when the air is clear, and therefore larger. Moreover, when suitable terrestrial objects happen to be placed near the horizon, they add very much to the effect. When, for instance, the moon sets near a tree some twenty feet in diameter, and about 1,000 yards off, as she subtends the same visual angle, and is known to be far more distant, she appears to be very much larger; whereas, when the moon sets behind a flat horizon, there is no object of comparison to enable us to perceive that her small *apparent* may represent a very great *absolute* magnitude.

"When I look at the moon reflected from a piece of parallel glass, so that her image appears to be very near the horizon, I do not find that the image looks decidedly larger than the moon herself seen directly high in the sky, although in this way it is easy to compare the apparent magnitude of the reflected image with that of the terrestrial objects seen together with it. In this case it is evident the reflected image has not the effect of being seen through the vaporous portion of the atmosphere.

"To my eye, the apparent increase in magnitude near the horizon is much more apparent in the case of the moon than in that of the sun. When the form of the sun can be distinguished at all, his light is generally so dazzling that we cannot look at him steadily, and consequently cannot compare him directly with any terrestrial objects that happen to be on the horizon. Even in the case of the moon when the sky is quite clear, the delusion is not so apparent. In all cases the delusion depends in a very great degree on the state of the atmosphere."

Occurrence of the Little Egret

An adult specimen of the Little Egret (*Ardea garzetta*, Linn.) was shot at the end of last month, on the mud-flats below Topsham, a town on the Exe, four miles below Exeter, and has unfortunately fallen into private hands. This is the first known occurrence of this beautiful bird on the Exe, but two or three specimens were recorded from the Dart and Tamar more than fifty years ago. The last specimen obtained in South Devon was killed in April 1851.

A nearly adult male Montagu's Harrier was shot near Christon, Devon, last month, and I have obtained it for the collection in this Institution. The female bird has since been seen.

Devon and Exeter Albert Memorial Museum, Queen Street, Exeter, June 13

Pinkish Colour of the Sun

In addition to the several accounts of the curious pinkish appearance of the sun, noticed in the numbers for May 26 and June 2 of your journal, it may perhaps interest your correspondents and the readers of Nature to know that the sun presented a round disc of a very unusual pinkish colour, here and at Cranbrook (about five miles north-east from Hawkhurst), in Kent, between five and six o'clock P.M. on the afternoon of Monday, the 23rd ult. It was so seen by myself at Cranbrook, in company with several others, who thought that the colour was quite unusual, shining through a thick haze of apparently low cirrostratus, but which was perhaps rain cloud, as the air at the time was light from the north, and cold, while the mist, or haze, seemed to be at no very great elevation above the ground, and considerably lower than those ordinary forms of cirrostratus in which halos and mock-suns are generally seen.

The colour observed here was a pinkish buff, or such a mixture of pink and yellow as to suggest the abundance of more blue and violet, and the absence of more yellow light than in the orange and reddish tints, generally seen in the setting sun, so as to resemble the colour of very pale blotting-paper, or a light flesh-colour. While the disc was still clearly seen of this colour, two or three sun-spots were visible upon it with the naked eye. These could no longer be distinguished at six o'clock, when the peculiar pinkish hue was also succeeded by the ordinary yellow of the sun's disc near the horizon, seen through a thick haze. On the same afternoon (of the 23rd) the appearance of the sun's round disc through a thick cloud of haze in the sky was noticed, for a considerable time, as visible with rare and unusual distinctness at Tunbridge Wells, in Kent.

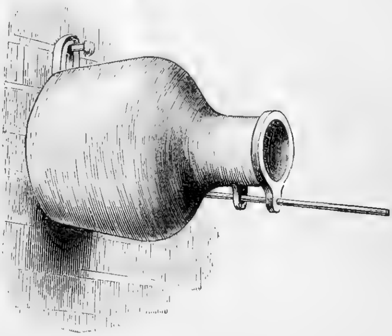
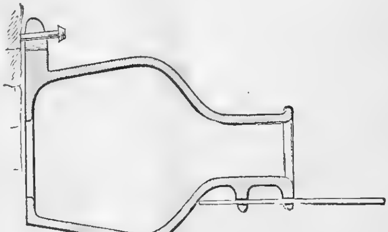
La Petite Culture en Belgique

I enclose drawings of earthern pots, which I observed nailed against the south side of a farm-house near this. These pots are for sparrows' nests, and the young, when fledged, are taken





and eaten. I think this form of "La petite culture" cannot be commended in a country so swarming with insects as Belgium, and I infer from the careful make of the pots that the custom is not a new one, though it may be new to some of the readers of Nature.

Louvain, June 4

The Report of the Meeting of the British Association for the Advancement of Science

It would be a great boon to the English public if the papers which are read before the members of the Association, or rather those who have the means as well as the inclination to attend such important annual gatherings, could be published within the first few weeks immediately after the meeting, and at such a price as many in this land would by no means grudge. According to the present arrangement, some months have to pass before even such as can afford the heavy price placed upon these reports can obtain them, the result of which is, that the poor and meagre reports of the various newspapers are all that the majority of persons have to inform them about the advancement of science. Could not some such report as that authorised by the committee of the Church Congress be produced? The first Congress was reported fully, the papers entire, and the discussions almost so, in a well-printed volume of nearly 500 pages, for the moderate sum of half-a-crown, prepaid; or four shillings if purchased afterwards. There are many, I am convinced, who would gladly prepay three or even four half-crowns for the report of the papers only which are read before the British Association.

Birkenhead G. H. H.

TERRESTRIAL MAGNETISM

The great progress made during the last few years in our knowledge of the phenomena of terrestrial magnetism has naturally attracted not a little attention to this interesting subject, and the persevering efforts of many leading scientific men are the surest guarantee of the ultimate success of the labours undertaken in this cause. Hitherto theory has gone hand in hand with observation, and those most able to undertake the charge are now only waiting a more complete array of facts, in order to present us with a theory of terrestrial magnetism based on solid foundations, and equal in interest, in completeness, and in the utility of its practical applications, to any of its sister sciences. The required facts may be ranged under these two heads. First the actual values of the magnetic elements at all parts of the earth's surface, with the secular variations of these elements; and secondly, the daily, monthly, and yearly range through which these quantities vary, and the irregular perturbations to which they are subject. To meet the first demand, a complete set of magnetic observations must be taken in different countries, the stations of observation not being too far distant from each other; and a repetition of these at intervals of from ten to twenty years will supply an accurate record of the secular variations of the required elements. The second need can only be satisfactorily provided for by the establishment of permanent magnetic observatories, supplied with self-registering magnetographs, by which every change of the magnetic force can be correctly traced.

Fortunately much has already been effected, and more is actually being carried out for the furtherance of this latter object. This country alone possesses three such observatories, Lisbon another, Florence a fifth, and four others are at present in course of erection, at St. Petersburg, Bombay, Melbourne, and the Mauritius. The fact, now clearly established, that any disturbance of the magnetic needle traced by our magnetographs in England has a corresponding perturbation recorded at Lisbon and at Florence, is an earnest of what we may expect from a careful comparison of magnetograms from all quarters of the globe.

But the other branch of observation, on which the determination of the absolute values of the magnetic elements solely depends, has scarce kept pace with the giant strides of the fixed observatories. Doubtless a series of monthly absolute readings is being taken at each magnetic observatory to serve as a basis for the differential curves traced by the magnetographs; but such observatories will always be few in number, and the accurate determination of the magnetic elements of these few points, however useful it may be, will scarcely suffice to give us a complete knowledge of the magnetic condition of the earth's surface. The survey of the ocean we may well trust to the devoted and persevering enterprise of the naval officers, who are adding so much to our store of meteorological and magnetic knowledge; but for the land surveys we must mainly depend on the accurate observations of private observers. A very limited number of scattered observations made at stations remote from each other, and the careful survey of scarcely half a dozen countries of Europe, is all we can point to as at present accomplished. If it be true that labour and expense are the great obstacles to be overcome when an important enterprise has to be undertaken, we may well wonder that the more laborious and by far the most expensive of the observations needed for the science of terrestrial magnetism are being amply supplied by the establishment of fixed observatories, whilst the magnetic surveys, which may be now made an agreeable pastime, and need scarcely add perceptibly to our usual expenses, are nearly entirely neglected. Most men who are daily engaged in intellectual occupations, require yearly a few weeks of repose, or at least of mitigated application. For many, some interesting work that does not too much engross their minds, and that differs considerably from their usual routine duties, offers a means of relaxation far more enticing than a complete cessation from labour. For men of this class, who have had some little experience in the use of instruments of precision, a magnetic survey might offer the greatest attraction during a summer vacation. A brief sketch of a simple method of carrying this into effect, which has been found to work well during two successive vacations, may not therefore be without its utility and interest.

The country chosen for a rapid survey should be one that offers considerable facilities for railway communication; and a previous study of the direction of the lines will prevent much unnecessary expense and loss of time from travelling twice over the same ground. Should the railway arrangements of the country resemble those of France, a companion for the journey becomes an absolute necessity; for the instruments used are of too delicate a make to be entrusted to the tender mercies of foreign railway officials of the registered baggage department.

The instruments required for the survey are a dip circle, an unifilar, a small transit theodolite, and a good chronometer. Two tripod stands are nearly a necessity if time be any consideration. Three days might conveniently be allotted to each station; one for travelling, another for the observations, and the third for visiting the objects of interest in the vicinity. Twenty sets of observations would thus be completed in the course of two months; and two vacations so employed would furnish data sufficient for the accurate study of the magnetic condition of an extensive tract of country. But should the time at the observer's disposal be more limited, and he feel equal to the task, the day of travelling might reckon as a day of rest, and the public monuments be visited during the leisure hours of the day of observation.

Arrived at a station, the first thought should be about the choice of a fit place of observation. The garden of any large public institution will perhaps in general be found the most convenient and accessible, unless an extensive and somewhat retired garden be attached to the hotel. Inquiry must next be made about the position of any considerable mass of iron, such as large pipes, which serve not unfrequently to convey gas or water at a few feet below the surface of a gravel walk or a grass plot. For the observation of the dip and the intensity, a good shady spot is required; whilst, for the declination, a position well exposed to the sun, at the early hours of the morning, is the best possible. A tent may sometimes be required to supply the want of trees; but when a large canvas covering, with poles, &c., has been carried from the north of England to the Pyrenees without ever being asked to do service, one is more inclined to trust in future to the resources of any locality, rather than again to travel in company with such a burdensome luxury.

Provided the morning be not hopelessly cloudy, it will generally be found preferable to start work by observing the declination. This choice may at times save the travellers a day or more of precious time in changeable weather; for the sun then not unfrequently shows himself for a short time in the early morning hours, and when the clouds have been permitted to close around him, he remains persistently hidden for the remainder of the day. For finding the magnetic declination, the sun is our most useful helpmate; but during the rest of the observations his presence can with benefit be dispensed with. The unifilar is therefore at once put together, and whilst the torsion of the silk thread by which the declination magnet is about to be suspended is being removed, the theodolite is fixed on a tripod stand, and several transits of the sun are taken over the vertical wires. The azimuth circle having been read at each passage of the sun, the telescope is placed horizontal, and the position of a fixed mark determined. A few altitudes of the sun might then be taken, for finding the error of the chronometer, before removing the theodolite from the tripod stand to make way for the unifilar. Great care must of course be taken in levelling each instrument before commencing an observation; and, after railway travelling, all the screws should be well examined. The tripod stand remaining firmly fixed in its first position, the unifilar is placed upon it, and the telescope is directed to the fixed mark and its azimuth read. The magnet is then suspended, brought to rest, and the positions of the azimuth circle and of the magnet scale noted. A second reading of the scale is afterwards taken in the inverted position, and this invertion should be twice performed, for greater security. A glance at his note-book will at once tell the observer whether he has entered all the data necessary for the future calculation of the declination. The chronometer gives the azimuth of the sun for a known latitude and longitude, the sun fixes the chosen mark, and the angle between the magnet and the mark then tells us what are the bearings of the compass at the station of observation. Having thus secured the declination, an interesting set of scale readings may be taken whilst the magnet still remains suspended. These readings, if taken every five minutes during any considerable time, will furnish materials for a comparison with the magnetograms of the fixed observatories; and thus afford satisfactory data for determining the relation that exists between the magnetic perturbations at different points of the earth's surface.

The dip circle is the next instrument to which attention must be directed. The observation of the dip of the magnetic needle is in theory the simplest, and in practice the most trying work of the survey. To attempt it when the atmosphere is saturated with moisture may be an excellent exercise of patience, but can scarcely lead to any trustworthy results; and a dusty locality will easily give the observer hours of labour before he has finished with a single needle. At each station, two or three needles should be used; each observation being the mean of 32 readings taken in different positions of the instrument and needle. The method of observation can offer no difficulties; after levelling the instrument, the needle is magnetised and gently lowered until it rests on its agate planes. The dip circle is then turned round till the needle takes up a vertical position; the reading of the azimuth circle at this point, when increased by 90 degrees, gives the direction of the magnetic meridian. The instrument may now be clamped with the needle in the meridian, and the readings of the angle of inclination commenced. Whilst the dip is being found, the torsion may be removed from the silk thread that serves to suspend the vibration magnet.

A complete knowledge of the direction of the earth's magnetic force at the station of observation having been acquired, it remains to determine the intensity of this force. Knowing the direction, it suffices to measure the intensity of the force in any given direction, in order to ascertain the total effect of the force. The horizontal component of the intensity is then the only element that still remains to be observed, and this is found by the method of vibrations and deflections. A magnet in the form of a small telescope, having a delicately graduated scale at the end farthest from the observer, is hung by a thread, and made to vibrate through an arc of a few seconds. The time occupied by 100 such vibrations is noted by the chronometer to within the twentieth of a second, and this is repeated some twelve times to obtain an accurate measure of the time of one vibration. The square of this interval of time serves to determine the product of the horizontal component of the earth's magnetism, by the magnetic moment of the vibrating magnet.

The quotient of these same quantities is next ascertained from the deflecting power of the vibration magnet. For this purpose another magnet is suspended by a very delicate silk thread, from which the torsion has been removed, and the vibration magnet is placed on a graduated brass bar at known distances from the suspended magnet. The opposite poles of the deflecting magnet are then presented alternately to the centre of the free magnet, and at the same distance due east and west. The various readings of the azimuth circle, and of the scale reflected by the mirror of the deflected magnet, are noted for each position, and the changes of temperature, which enter into the results, are frequently recorded.

The series of observations is then completed, and, when the instruments have again been packed with all possible care, the observers are ready for the journey of the morrow. Very much of the success of the survey depends on the steady rate of the chronometer; and hence no pains should be spared to preserve it from all jolting movements whilst travelling, and altitudes of the sun should never be omitted. But it is, above all, advisable to lose no opportunity of comparing the chronometer at any good observatory that can conveniently be visited on the way.

A full set of the above observations may be taken by one person within the space of half a dozen hours, but then all must have gone on smoothly from starting to the end. A loud clock, a clear-toned bell, or even the rustling of the leaves in a high wind, will not unfrequently compel an observer to recommence his series of vibrations. Or again, the breaking clouds will entice him out with his theodolite, and then the sun will always seem purposely to hide himself at the moment he approaches the fatal wire. But the near approach of friends is what tries most the powers of endurance. The second has arrived for taking the observation, the eye and ear are all attention, and a person shows his interest in the work by spoiling all with an ill-timed question. Or again, the suspended magnet is just coming to rest after a tedious oscillation, the observer's patience is about to be rewarded by a perfect reading, when a violent movement of the magnet makes him aware that the bunch of keys or pocket-knife of a friend, who approaches with the most scupulous avoidance of all noise, have attracted the attention of the giddy little needle. But a good observer will never be overcome by such trifling difficulties.

A two months' vacation passed in this alternation of travel, observation, and repose, will witness the accumulation of data sufficient for the calculation of the isogonics, isoclinals, and isodynamics of a large extent of country, and the observer will return to his routine labours invigorated in mind and body, and with the consoling thought that he has added some little at least to that mass of well-established facts, which must ever be the only foundation of any true advancement in the Natural Sciences.

S. J. PERRY.

COFFEE

CONSIDERING the fact that the necessities of our daily life, whether as clothing, food, or medicine, are mostly provided by the vegetable kingdom, it is remarkable how little is generally known of the sources from whence we derive our most common articles of commerce. We propose in this article to say something about our Coffee, and especially about the mode of detecting whether the commercial article is pure or adulterated.

Although the specific name of the coffee plant, *Coffea Arabica*, appears to indicate the coffee tree to belong originally to Arabia, it is with good reason supposed to be a native of the mountainous part of the south-west point of Abyssinia, having been introduced from thence into Arabia, where it is said to have been first used about 1450. For about 200 years after this date the whole of the coffee used was grown on Arabian soil, from whence the Dutch introduced the plant into Batavia, after which it was carried into other eastern countries as well as into various parts of the western hemisphere. The introduction of coffee into Europe took place about the middle of the sixteenth century, fourteen years before the introduction of tea.

Fig. 1.—Branch of Coffee Plant.

The fruits of the coffee tree when ripe are gathered and taken to the pulping house, and placed in a machine called a pulper, by which the fleshy covering is removed, the beans or seeds pass into a cistern, and the pulps are carried off in another direction and are collected and preserved for manure; the seeds themselves are left to steep for several hours, so as to soak off any remaining mucilage or pulpy matter; they are then washed and dried, the parchment and the thin inner skin being removed by winnowing, after which they are packed in bags and ready for shipping.

The berries or seeds of true Mocha coffee, which is, however, now scarcely to be obtained in Europe, are usually more round than those of other varieties; they nevertheless vary much in form as well as in size and colour; and though the several commercial sorts are easily known to a practised eye, they are difficult to detect by an ordinary observer. The value to the consumer does not in all cases depend so much upon the size or shape of the seed as upon its flavour and the strength of its aroma, but these qualities cannot be discovered until after roasting; therefore in purchasing unroasted coffee, an important point is to see that the seeds are not damaged by sea water or mouldiness. In roasted "whole" coffee, the case is different, for a greater or lesser aroma of more or less fragrance can be detected, the volatile oil, and the peculiar astringent acid to which the aroma and flavour are due, and which before were latent in the seed, being developed

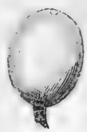

Fig. 2.—Coffee Berry (*nat. size*).

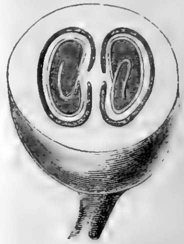

Fig. 3.—Section of Coffee Berry (*magnified*).

by the heat. In the process of roasting, the seeds lose about one-fifth in weight, but increase in bulk by about one-half.

The peculiar principle of coffee is called caffeine, and is identical with that of tea; it acts as a stimulant upon the brain, preventing sleep or drowsiness, and causing greater mental as well as bodily activity; it is also said by some chemists to repair or prevent in a remarkable degree the too rapid waste of the tissues, so that life can be sustained on a smaller quantity of food than would be the case without the use of coffee.

Understanding these principles which Nature has given to coffee, and which Science has revealed for our benefit, we cannot fail to see the great importance of obtaining the article in its genuine state. Upon microscopical examination, genuine coffee can be easily detected, the cells of the coffee-seed being very irregular in form, and having very thick walls with ragged sides. Some of these ragged projections belong to the true cell wall, while a few are composed of starch granules. Genuine coffee, then, should always present this appearance, for there are no tubes or spiral vessels in the true coffee seed as there are in the root of the chicory; and moreover, in the cellular part of the chicory root, the cells themselves are larger, the walls are shown as mere fine lines, closely fitting together by the pressure exerted upon them in the process of growth. This difference will be more readily understood by reference to Figs. 4 and 6. In the most genuine coffee, however, a certain portion of the skin must be present, the microscopical appearance of which is shown at Fig. 5; by reference also to Fig. 3, it will be

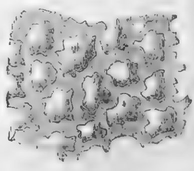

Fig 4.—Tissue of Coffee Seed, after being roasted and boiled.

Fig. 5.—Microscopical appearance of Coffee Skin, after being roasted and boiled.

seen how a portion of this skin is naturally enclosed in the folds of the seed, so that, while in the process of cleaning it is entirely removed from the surface of the seed, the enveloped portion remains, as it cannot be removed without breaking or injuring the seed. This, however, has been done in the trade, and a series of coffees was exhibited in the Great Exhibition of 1851, amongst which were roasted coffee seeds which had been divided longitudinally by a patented machine, and the folded skin taken out; these broken seeds were sold under the name of coffee nibs. We do not see any advantage in this; but on the contrary, the broken seeds would be much more liable than whole seeds to adulteration with damaged berries, and this skin is so thin that it adds little to the weight of the coffee, and the small proportion in which it occurs does not affect either the pocket or the health of the consumer; indeed, we are told by some travellers, that neither the skin nor the parchment itself deteriorates the quality of the coffee, but rather adds to its value, for in some parts of Arabia the parchment is preferred before the seed itself.

Therefore genuine coffee, when seen under a microscope, will exhibit an appearance similar to that shown at Fig. 4, with the addition, in nearly all cases, of a few small bodies like those at Fig. 5, scattered here and there.

A very simple test for the presence of chicory in ground coffee, is to drop a little in a tumbler of clean cold water. Do not stir it, but if chicory is present the particles will immediately drop to the bottom of the tumbler, imparting at once to the water a deep amber colour; the coffee particles will float for a much longer time, and the water

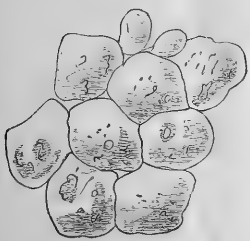

FIG. 6.—Cellular Tissue of Chicory.

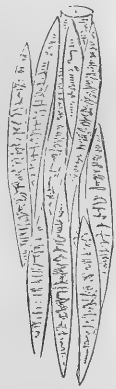

FIG. 7.—Vascular Tissue of Chicory.

will be but slightly coloured. The most satisfactory way of purchasing coffee, however, is in the whole state, and to grind it as it is wanted, when all the freshness of the aroma is obtained in the infusion. For examination under the microscope, coffee should be previously soaked in water, or boiled in a weak solution of potash; this both softens the tissues and makes the substance more transparent. For persons unacquainted with vegetable structure, it will help them very much in determining the microscopical appearance of genuine roasted coffee, to examine first both the fresh coffee seed and the fresh chicory root; for this purpose a slice should be cut from each as thin as possible, moistened with water, and placed on a glass slide with an ordinary thin glass covering dropped on the top, and gently pressed down with the fingers so as to exclude all air bubbles. A half-inch objective may be used, and with an ordinary amount of perception adulterations may be detected. Other substances than chicory may be mixed with coffee, but none will present such microscopical appearances as those we have shown to belong to genuine coffee.

J. R. JACKSON

NOTES

WELL-WISHERS of the University of Oxford will rejoice to hear that the honorary degree of D.C.L. has been offered to Mr. Darwin. The state of Mr. Darwin's health unfortunately precludes him from accepting the proffered honour, but the scientific naturalists of this and other countries will none the less appreciate the compliment which has been paid to their great leader. It is all the more graceful as Mr. Darwin is not an Oxford, but a Cambridge man, a circumstance which the University of Cambridge seems to have forgotten; though by-and-by it will be one of her claims not to be herself forgotten.

DR. HOOKER, F.R.S., and Professor W. H. Flower, F.R.S., have been appointed examiners in botany and anatomy for the Natural Sciences Tripos at Cambridge. The other examiners are Professor Miller, Sec. R.S., in mineralogy, Mr. Trotter, fellow of Trinity College, in chemistry and physics, Mr. Danby, fellow of Downing College, in geology.

WE are glad to announce that Mr. Geikie has arrived in England, and is in a fair way of recovery.

THE Sars subscription fund has now reached 343*l.* in England, and 11,666 francs in France. It is very desirable that intending contributors should forward their subscriptions without delay.

IT is reported that the Secretary of State for India has determined upon establishing in this country a complete College of Science for civil engineers, for the education of those who are to be employed on the extensive Government works in that country.

ALL true lovers of science will be glad to hear of the approaching visit to this country of Prof. Henry, the Secretary of the Smithsonian Institution at Washington, United States. It is well known how much our own celebrated electricians are indebted to Prof. Henry for his valuable researches in magnetism and electricity, the results arrived at being freely placed at the disposal of all whom they might interest. We understand he is daily expected.

THE celebrated photographer, M. Niépce de St. Victor, having died in very straitened circumstances, leaving a wife and two children totally unprovided for, a committee of French photographers has been formed to collect a fund for their relief. Subscriptions may be forwarded to MM. Blacque and D'Eichthal, bankers, 19, Rue de Grammont; or to the president of the French Photographic Society, 9, Rue Cadet, Paris.

IN the Rev. William Hincks's address as President of the Canadian Institute, we find the following sentence:—"If we may implicitly believe a statement in the new periodical devoted to natural science, NATURE, whilst the English are still discussing the possibility of Darwinianism being true, the Germans have so thoroughly adopted it that it has become the foundation for new systems—the starting-point for fresh inquiries. This may appear to most of us to be going somewhat too fast; but then NATURE may be presumed to be the special organ of the extreme Darwinians, and might be thought to see facts through a somewhat coloured medium." It will hardly be necessary to point out to our readers that we are the organ of no party, extreme or otherwise. Free play has been given in these pages to the expression of opinion by competent men of every section or party. In so far as "Darwinianism" implies rigid accuracy of observation and a candid consideration of all the varied phenomena of natural science, we trust we shall always be Darwinian as we hope to be Newtonian.

A. H. GARROD was elected on the 13th inst. a Foundation Scholar of St. John's College, Cambridge, for proficiency in the Natural Sciences; at the same time H. Blunt and H. N. Read were elected, for the same cause, to exhibitions of 20*l*. and 10*l*. respectively. Mr. Garrod obtained in 1868 the Natural Science exhibition of 50*l*. per annum, open to students commencing their residence.

THE committee who organised courses of lectures for women at Cambridge last year have issued the following scheme of lectures for the academical year 1870-71. They will be delivered, generally speaking, twice a week within the period of University residence:—English History, by Professor Seeley. English Literature, by W. G. Clark, M.A., and others. It is proposed to give a series of short courses on different departments of English literature. They will be delivered once a week during the October Term, certainly, and, if possible, during the whole academical year, commencing with a course on "Shakespeare and the Elizabethan Dramatists" by Mr. Clark. English Language and Literature, by W. W. Skeat, M.A.; Latin, by J. E. B. Mayor, M.A., and A. Holmes, M.A. (Elementary Lectures); Greek, by J. Peile, M.A.; German, by W. C. Green, M.A.; French, by M. Boquel; Algebra and the Principles of Arithmetic, by Professor Cayley; Practical Arithmetic, by J. F. Moulton, B.A.; Geometry and Elements of Physics treated Historically, by W. K. Clifford, B.A.; Logic, by J. Venn, M.A.; Political Economy, by A. Marshall, M.A.; Geology, by T. G. Bonney, B.D. (Botany, by Professor Babington, will be substituted for Geology in the Easter Term); Chemistry, by P. T. Main, M.A.; Harmony and Thorough Bass, by G. M. Garrett, Mus. D.; Theory of Sound in its application to Music popularly and experimentally treated, by S. Taylor, M.A. All persons wishing to attend any of these lectures in the next October Term are requested to apply to the Rev. G. F. Browne, St. Catherine's College, on or before the 1st of October. The committee announce the following Exhibitions:—One of 40*l*. per annum for two years, to be given to one of the senior candidates in the Cambridge Local Examinations, January, 1871, according to the report of the examiners. Attendance at two courses of lectures in every Term will be required as a condition of receiving the Exhibition in each year. Given by Mr. Mill and Miss Taylor. One of 20*l*. for one year together with free admission to three courses of lectures in each Term; and one of 10*l*. for one year. Given by Mrs. Adams. These two will be given by two of the candidates in the Cambridge Examination for Women, July, 1870, according to the report of the examiners. Attendance at two courses of lectures during each of two Terms at least will be required as a condition of receiving either of these Exhibitions.

THE following elections to scholarships have been made at Gonville and Caius College, Cambridge: G. Warington, 50*l*., for chemistry; G. J. Romanes, 20*l*., for anatomy and physiology. We hope that this College, which has been peculiarly prolific in eminent medical men, will soon follow the example of some of its neighbours in offering open scholarships for Natural Science.

DR. ALBERT WALSH was elected, at a meeting of the Royal College of Surgeons of Ireland, held on the 13th inst., as president of the college for this year, and Dr. Wharton was elected vice-president. The only alteration in the council was the election of Dr. Butcher, by a small majority, in place of Dr. Mapother.

THE examination for the vacant fellowship in Trinity College, Dublin, commenced on the 30th May, and concluded on the 11th inst. The following numbers represent the highest possible answering in each of the three courses. Mathematics, 1,250 (pure 1,000, experimental science 250), classics 750 (classics 650, Hebrew and cognate languages 100), mental and moral science 500. The election took place on Trinity Monday, when George Cathcart was elected fellow and the Madden Prize was given to W. S. Burnside.

THE *Academy*, referring to Mr. Lockyer's recent observations that the various vapour-currents in the solar envelope, which has been called the chromosphere, and defined as possibly the outer layer of the sun's atmosphere, were so rapid and violent that the position of the hydrogen lines in the spectrum was altered, and that by noting the amount of alteration, the actual velocity of these "solar storms," as Mr. Lockyer has termed them, could be determined without difficulty; states that Father Secchi, of Rome, who a long time ago denied the accuracy of these observations, and the validity of these conclusions, has quite recently returned to the charge. Father Secchi asserts that the alterations observed in the wave-length are really due to the *sun's rotation*, and then he proves by calculation that the velocity of the sun's surface at the equator is 429 kilometres per second. He next calculates what alteration this motion should make in the position of the hydrogen lines in the spectrum; and last of all he points his spectroscope to the sun and sees exactly such alterations as his calculations require. Now this at first appears a final answer to Mr. Lockyer, but Volpicelli and Fizeau have pointed out that Father Secchi's calculation in fact shows him to be ignorant of Mr. Lockyer's reasoning, and that his 429 kilometres per second should really read two kilometres.

THE *Gardener's Chronicle* congratulates us on finding that our friends across the Channel have as characteristic a Circumlocution Office as ourselves. Here is what the French papers say on the matter:—A provincial druggist, desirous of gathering Fox-glove (*Digitalis*) in one of the State forests, applied for permission to the local authority (*garde général local*), offering at the same time to pay an annual sum of six francs for the privilege. The local magnate transmitted the request to his inspector, who forwarded it to the Conservator of the department, who despatched it to Paris to the Director-General of Forests, who caused it to be sent to the Minister of Finance. The Minister referred it "for study" to the Director-General of Domains, who sent it to the Departmental Director of Domains to be examined by the Registrar. The latter, after examination, pronounced a favourable opinion on the request, and sent it back to the Departmental Director, who forwarded it to the General Director, who, in his turn, despatched it to the Minister, through the agency of the General Secretary of Finance, who availed himself of the opportunity to make his comments on the matter. Then the unhappy druggist's request was returned to the Director-General of Forests, who sent it to the Conservator, he to the inspector, and the inspector to the *garde général*, who was the original recipient of the request. The authority "to cull simples," at length reached the successor of the original postulant, and at an age when he was too old to herborise. We hope this style of management will not be engrafted on to our Indian forest department, already well provided in this way.

THE lecture next Sunday evening at St. George's Hall, Langham Place, under the auspices of the Sunday Lecture Society, will be delivered by Mr. D. Forbes, F.R.S. The subject is "Volcanoes."

M. CLAUDE BERNARD commenced yesterday in the amphitheatre of the geological gallery his course of lectures on general physiology at the Museum of Natural History, Paris. He will treat of the general principles of physiology, especially from the point of view of its relation to the other sciences.

DR. MAXWELL T. MASTERS is engaged in editing a new edition of "Henfrey's Elementary Course of Botany," condensed, and in many parts re-written, which will be published in a few days.

DR. R. VIRCHOW has contributed to a recent number of the *Zeitschrift für Ethnologie* an interesting article on "Portrait or

Facial Urns" (*Gesichts-urnen*), which has been printed separately. Funereal urns, containing bones and ashes, have long been known, in museums, from Egypt and Etruria, the lids of which, generally of stone, were fashioned into the shape of a human head, or that of some other animal. The human heads, if not portraits, are supposed to have at least indicated the condition of the deceased. In the course of the last forty years facial urns have been discovered in mounds in various parts of Germany, mostly near the Roman settlements on the Rhine, but more recently in the neighbourhood of the watering-place Zoppot in Pomerania, but confined to a very circumscribed district, and exhibiting, according to Dr. Virchow, points of marked difference from those found in Rhenish Prussia. Many of these have well-developed human faces, others have rough drawings of animals, sometimes difficult to make out, scratched upon them. Similar urns are described as having been found in Mexico and Peru; but Dr. Virchow believes that the peculiar contour and form of ornamentation of these North German urns indicate an Etrurian origin, and possibly point to a colonising of the Baltic from Italy.

AT the last meeting of the Scientific Committee of the Horticultural Society, the Rev. M. J. Berkeley exhibited some specimens of the female form of *Lychnis diurna*, in which the flowers were infested with smut, and the stamens, usually abortive, were developed. Mr. Berkeley believes that "the *Ustilago* penetrates the plant, but as it can only fructify in the stamens, it would appear to be the determining cause of the production of those organs in the normally female flower." It is laid down as a rule in Mr. Darwin's works that no change can take place in a species through the agency of Natural Selection unless the change is for the benefit of the species. It is difficult to see how the abnormal production of stamens for the purpose of finding a home for the smut can benefit the *Lychnis*; and it would be interesting to know whether vegetable physiologists generally will sanction the idea of such a power in the plant to develope organs which assist in its own destruction.

WE have received a letter from Mr. Walenn pointing out that in our report of the meeting of the Chemical Society on May 19, we have omitted to mention that the calico-printing roller which was exhibited was immersed for some days in a bath containing sulphuric acid and cupric sulphate, then coated with brass in an alkaline liquid, and finally coated with copper in an acid bath. A deposit, $\frac{3}{16}$ of an inch thick, weighing 29 lbs., and of compact copper, was thus produced.

THE *Chemical News* describes a new method of heating stoneware vessels, and of obtaining regulated high temperatures, which will be of considerable importance in conducting chemical and pharmaceutical operations for manufacturing purposes. By this new method, which has been patented by Mr. J. A. Coffey, the pharmaceutical engineer, any temperature ranging from 100° to 700° F. can be safely and easily obtained. The principle is to cause heavy paraffin oil to circulate, first through a coil of pipes in a furnace, and then through the jackets of the pans. It moves by its own convection. As contrasted with steam-heat, the inventor claims for his process a saving of 30 per cent. in fuel, the large amount of heat necessary to convert water at 212° F. into steam at 212° being economised.

"THE Autotype Process: being a practical manual of instruction in the art of printing in carbon or other permanent pigment," is a handsomely-printed pamphlet of 48 pp., very clearly written, and describing all the modern improvements in the process, which are considerable. It is divided into five parts, which treat of the nature and history of carbon printing, its general practice, its special practice for non-inverted pictures, its special practice for inverted pictures, and concluding observations

ETHNOLOGY

The Meenas of Central India

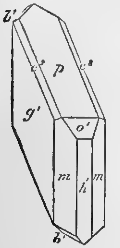
LIEUT-COL. C. L. SHOWERS has communicated to the Proceedings of the Asiatic Society of Bengal, a paper upon the Meenas, a wild tribe of Central India. Lieut.-Col. Showers says, that when the Meenas first fell under his observation in the year 1854, they were in a condition of entire lawlessness. Emboldened by long impunity they carried their audacity so far as to attack and pillage several walled towns in the British district of Ajmur, carrying off not only the entire plunder to their hill fastnesses, but numbers of the inhabitants also, holding them to ransom. At that period it fell to the duty of Lieut.-Col. Showers to take them in hand. He proceeded to Jehazpoor, the centre of the disturbed district, and inaugurated certain measures for the tranquillisation and reclamation of the race. From time immemorial, Jehazpoor, in the State of Adeypoor, had been a notoriously disturbed district. A period of brief tranquillity was accorded to Jehazpoor during the early part of the present century by the appalling severity of the measures of the noted minister Lalim Sing, after Jehazpoor fell into the possession of Kotah in 1806. On the restitution of the district, however, to Meywar, in 1819, it soon relapsed into its former disturbed condition. Jehazpoor was, in truth, a position well chosen for the lawless occupation of professional marauders, being a strong, hilly, and jungly country, where the boundaries of four jurisdictions meet, viz.—Meywar, Boondee, Jeypoor, and Ajmur. There are twelve tribes of Meenas in Central India, but the one under notice is called the Purihars, who were the dominant race in Marwur, till dispossessed of their ancient capital Mundore by the Rhatees towards the close of the fourteenth century. In a generation or two afterwards they are found in the Chronicles lurking on the quadruple boundary already alluded to, a race of outcasts without a common head; and such they have continued ever since, "their hand against every man, and every man's hand against them," plundering in gangs and joining any of the great marauding movements that have from time to time been organised under noted leaders. Thus in 1847, some of the boldest of the outlawed Thakur Javahir Singh's followers were these Meenas. The same indomitable spirit which carried the Purihars forth out of the land of their lost dominion seems to have maintained them in a state of wild independence throughout the long interval since; for though nominally owing allegiance to the States upon the verge of whose territories it has suited their purpose to locate themselves in *fallahs* or gangs, they have never really succumbed to any power, but, hanging together as one man, have always united to repel the frequent futile attempts that have been made from time to time by the rulers of States to coerce any of their Meena subjects, so-called. The aggregate of male adults in the tribe is about 24,000; of this number about 10,000, distributed in 200 villages, are located along these border tracts. Individually the men are brave to desperation, athletic and hardy, many of them tall with fine countenances, denoting their superior origin. The Meena will neither eat, smoke, nor intermarry with the aboriginal Buhl, Mair, Kole, or low-caste Meena of the Aravulla; that is to say, he will not give a daughter in marriage, though he will take to his bed as many daughters of inferior tribes as he can support. Their pride of birth is indeed excessive, fostered by traditions ascending beyond the bounds of history to the regions of myth. The genealogist of the tribe is the honoured guest in every village he visits in his annual round. Each family engages his company for one entire day, which is occupied in recording in the ponderous MS. volume the recent additions to the family tree, whether in the male or female branch; for even the ancestry of the women is duly recorded. About half the tribe are armed with matchlocks of a superior manufacture, about half with the bow, and all with the kattar, or double-hilted dagger, which is a weapon they peculiarly affect. It is a weapon never detached from the person a moment, waking or sleeping. Free from the ordinary prejudices of caste, the Purihars are great eaters of meat, which their cattle-lifting raids furnish in profusion. They are also great drinkers of spirits, which serve to increase their natural ferocity. All are married, and many besides take in keeping the widows of their deceased clansmen to the number of two or three each, or otherwise forcibly domicile women abducted in their raids. Perhaps the most noteworthy fact relating to the tribe was their ignorance, up to the day of Lieut-Col. Showers' arrival among them, of the true character of the British Government as the paramount power.

The raids of the Meenas into British territory brought matters to a crisis, and it became necessary to put them down. But in contrast with the unfortunate contests with savage races, which are going on at the present day in other parts of the world, it may not be unworthy of note that the tranquillisation of Jehazpoor was effected without a shot being fired.

CRYSTALLOGRAPHY

Crystals of Potassic Racemate

ACCORDING to De la Provostaye, potassic racemate crystallises in the rhombic system; but M. des Cloiseaux, in a communication to the Annales de Chimie (xvii. 365), disputes the truth of that statement. All the crystals with which he worked (some being presented to him by Pasteur, some by Lamy and Gernez), are really derived from an oblique rhomboidal prism of 96° 56′. The base of this prism is always highly developed, and its inclined diagonal makes an angle of 92° 28′ with the anterior vertical edge. The plane of the optic axes is perpendicular to the plane of symmetry; the acute bisectrix is negative and normal to g'. The *revolving* dispersion is considerable, as shown by the distance which separates the plane where the red axes are situated from that containing the blue. It is easily found by the polarising microscope across fine sections, normal to the acute bisectrix. The *proper* dispersion of the axes is rather strong, with $\rho < \nu$. For their apparent distance in air (at 19)



$2E = 130\ 2'$ (red rays); $132\ 45'$ (blue rays).

ZOOLOGY

Development of Molgula Tubulosa

IT is well known that the larvæ of the Ascidians generally possess a form resembling, in external appearance at least, that of the tadpoles of our common Frogs, and also resembling these in the agility with which they swim about by means of their tail-like appendage. In fact, as M. Lacaze Duthiers indicates in a paper just communicated to the Academy of Sciences, this peculiarity of development has for a long time been regarded as characteristic of all the Ascidians. According to the celebrated naturalist just mentioned, *Molgula tubulosa* forms an exception to this general rule. Instead of exhibiting the brisk, jerking movements of the embryos of the *Phallusiæ* for example, the embryo of *Molgula* moves very slowly within its egg-capsule, its movements consisting chiefly of alterations in its general form which, however, finally effect the rupture of the capsule. Through this opening the embryo *flows*, like a plastic, amœboid mass, which remains quietly at the bottom of the vessel, merely changing its form slowly by amœboid movements. Soon after exclusion the embryo shows indications of zones in its body, and from the outermost of these processes are given off (for some time only five in number), which seem to fix it to surrounding objects and are analogous to the innumerable filaments of the tunic in the adult.

SCIENTIFIC SERIALS

THE May number of Silliman's *American Journal of Science and Arts* (vol. xlix. No. 147) opens with a paper by E. W. Blake, jun., on a method of producing, by the electric spark, figures similar to those of Lichtenberg. His method consists in throwing the discharge upon the surface of a fusible non-conducting body, of which common pitch, coating a plate of tin, seems to furnish the best results. Figures produced by means of friction and induction sparks are represented by woodcuts. Col. J. J. Woodward publishes an important paper on the application of the magnesium and electric lights to photomicrography, illustrated with figures showing the arrangement of the apparatus. An anonymous writer, using the initials J. H. B. L., describes and figures a new form of mechanical finger for the microscope. The chemical papers are as follows:—Combinations of silicon with alcoholic radicals, by C. Friedal and J. M. Crafts, a long and valuable paper; analyses of meteoric irons, and remarks on the alkalies contained in leucite, by J. Lawrence Smith the first part of a memoir by B. Silliman and H. Wurtz, on flame temperatures in their relations to composition and luminosity; on some double sulphates of the Cerium group, by C. H. Wing; on two peculiar products in the nickel manufacture, by Joseph Wharton; two short notes by O. Loew, on the action of sunlight on sulphurous acid, and on the formation of ozone by rapid combustion; and two notes on methods to be adopted in gas-analyses by Dr. Wolcott Gibbs. Prof. Arthur Wright notices some curious phenomena observed by him in connection with the discharge of an electrical machine. Natural History proper is represented in this number only by two papers, namely, an account, by H. Y. Hind, of the Laurentian and Huronian series in Nova Scotia and New Brunswick, and descriptions of some new corals, by A. E. Verrill. The latter consist of four Alcyonaria and three Madreporaria, one of which is described as forming a new genus. Besides the usual abstracts and extracted articles placed under the head of Scientific Intelligence, the editors publish an extract from a letter describing the movements produced by a strong gale of wind in the great iron dome of the Capitol of Washington. This is illustrated by a tracing of the pencil mark showing the course of the movement of the centre of the dome.

THE *Revue des Cours Scientifiques* for June 4 gives us M. Berthelot's lecture "on the isomeric states of simple bodies," in which he treats especially of the different states of oxygen, and concludes by observing that there exists, at least in certain cases, a relation between the states of a simple free body (element) and the nature of the combination from which it has been separated; that a simple body in a certain condition can enter more easily into one class of combination than into another class; and that a simple body can change its condition even while it exists in certain combinations. We find also a continuation of M. Bernard's lectures on "Suffocation by the fumes of charcoal," and an address by M. C. Robin, entitled, "How the parts of an organism adapt themselves to determinate purposes." The number for June 11 is mainly occupied by the description of a contrivance by means of which a locomotive can be made to act as a drag or arrester of motion in the train, when such is the will of the driver. We have also a report of Prof. Helmholtz's lecture before the Society of Natural and Medical Sciences at Heidelberg, on "the physiological action of electric currents of short duration in the interior of extensive conducting masses."

THE *Journal of Botany, British and Foreign*, for June hardly sustains the interest of the earlier numbers of the new series. The original articles are confined to a continuation of the Hon. J. L. Warren's paper on the British *Rubi*, and of Mr. Worthington Smith's *Clavis Agaricinorum*, and an article of considerable interest to geographical botanists and theorists on the origin of species, "On the World-Distribution of the British *Caryophyllaceæ*," by Mr. J. G. Baker. We have besides a biography (with portrait) of the late Dr. Franz Unger, and some extracts and shorter notes.

THE best article in the May number of the *American Entomologist and Botanist*, is one which is neither entomological nor botanical, "On the Gordius or Hair-worm," by Prof. Jos. Leidy, of Philadelphia, giving an account of the anatomical structure of the animal, its mode of propagation, and of the different species found in the United States. There are several other articles and an abundance of shorter notes, that will be of value to the young naturalist.

THE *Geological Magazine* for June commences with an article by Prof. Harkness, on "Elephant-remains in Ireland," which have now been met with in several localities. The writer mentions incidentally that Ireland has afforded hitherto no traces of either the hyæna or lion; the pleistocene carnivora were confined to the bear, of which, however, there are no historical records, and the wolf, which was finally extirpated about the year 1710. Prof. de Koninck contributes a paper "On some new and remarkable Echinoderms from the British Palæozoic rocks, including a species of *Palæchinus*; a new species and new genus, *Placocystites Forbesianus*, belonging to the family of *Cystideæ*; and a new species of *Haplocrinus*, *H. granatum*." Mr. T. G. Bonney, "On supposed *Pholas*-burrows in Derbyshire," believes these burrows to have been made by a *Helix*. Mr. J. W. Laidlay describes a "Prehistoric Dwelling and Kitchen-midden on the Coast of Haddingtonshire," in which were found a very large quantity of rude pottery in fragments, and, for the most part, roughly moulded by the hands; a number of implements of bone, such as needles, arrowheads, combs, knives, chisels, &c.,

very similar to those found in the Swiss lakes; a vast quantity of bones of oxen (of several varieties, including *Bos longifrons*), sheep, goats, deer, swine, dogs, &c.; of shells a great abundance, especially those of the *Patella* and *Liottrina*; a very rude querne, &c. They are considered to belong to an age as remote as the Roman period, or perhaps extending even beyond it. Mr. J. Croll concludes his account of "The Boulder-clay of Caithness, a product of land-ice," and Mr. C. Lapworth his valuable paper "On the Silurian rocks of Galashiels." Mr. Croll considers that nearly the whole of the North Sea, between Scandinavia and Scotland, was filled with glacier ice at the time of the formation of the boulder-clay of Caithness; and he indicates facts in the glaciation of the Orkney, Shetland, and Faroe Islands which certainly go a long way in support of his views. It is also to this enormous extension of ice that he ascribes that of the Loess, by the daming up of the waters of the Rhine and Elbe. Mr. Croll's paper is illustrated with a map.

Annales de Chimie et de Physique. April, 1870.—This number contains a long and valuable paper by M. Berthelot on the Varieties of Carbon. He commences by pointing out the specific heats of five different kinds of carbon, and comparing them with the specific heat of the element as deduced from that of its gaseous compounds, and shows that the relations between specific heat and atomic weight are not the same as those observed in the case of other elements. He then explains his process for distinguishing and separating the varieties of carbon by treatment with nitric acid and potassic chlorate, and describes the products obtained from carbons of different origin, enumerating no less than thirteen different varieties of the element. The next two sections describe the effects of various agents on carbon, and the carbon obtained from different compounds; concluding with the observation that the kinds of carbon differ so widely in their properties, re-actions, and specific heats as almost to warrant their being considered as different elements. The four following papers are also by M. Berthelot. The first is on the oxidation of hydrocarbons by a strong solution of chromic acid, under which circumstances ethylene produces aldehyde, propylene gives acetone, amylene forms complex bodies, probably derived from an acetone, acetylene produces carbonic, formic, and acetic acids, whilst from camphene camphor is obtained. The second describes a new synthesis of phenol, by treating acetylene with fuming sulphuric acid, thus preparing acetyleno-sulphuric acid and decomposing the potassium salt with fusing potassic hydrate. It appears that at the moment of the liberation of the acetylene from the sulpho-salt three molecules condense and oxidise at the same time. The third paper is on the action of potassic hydrate on the sulphuric derivatives of the hydrocarbons, in which the author describes the products obtained from several of the sulpho-acids. He endeavoured to prepare methylene from sodic formeno-sulphate, but without success, and in consequence of the numerous experiments which he has made he thinks that chemists must give up hopes of its existence. The last paper is on a new synthesis of acetic acid by means of acetylene. The author has discovered several processes which effect this transformation. The last method is by digesting acetylenic dichloride with alcoholic or aqueous solution of potassic hydrate, when potassic acetate and chloride are formed. Acetylenic tetrachloride with alcoholic potash at 100° gives glycolic acid, and with aqueous potash at 230° oxalic acid.

SOCIETIES AND ACADEMIES

London

Royal Society, May 19.—"Spectroscopic Observations of the Sun." No. VI. By J. Norman Lockyer, F.R.S.

The weather has lately been fine enough and the sun high enough, during my available observation-time, to enable me to resume work. The crop of new facts is not very large, not so large as it would have been had I been working with a strip of the sun, say fifty miles or a hundred miles wide, instead of one considerably over 1,000—indeed, nearer 2,000 in width; but in addition to the new facts obtained, I have very largely strengthened my former observations, so that the many hours I have spent in watching phenomena, now perfectly familiar to me, have not been absolutely lost.

The negative results which Dr. Frankland and myself have obtained in our laboratory-work in the matter of the yellow bright line, near D, in the spectrum of the chromosphere being a hydrogen line, led me to make a special series of observations on that line, with a view of differentiating it, if possible, from the line C.

It had been remarked, some time ago, by Prof. Zollner, that the yellow line was often less high in a prominence than the C line; this, however, is no evidence (bearing in mind our results with regard to magnesium). The proofs I have now to lay before the Royal Society are of a different order, and are, I take it, conclusive:—

1. With a tangential slit I have seen the yellow line bright below the chromosphere, while the C line has been dark; the two lines being in the same field of view.

2. In the case of a bright prominence over a spot on the disc, the C and F lines have been seen bright, while the yellow line has been invisible.

3. In a high-pressure injection of hydrogen, the motion indicated by change of wave-length has been less in the case of the yellow line than in the case of C and F.

4. In a similar quiescent injection the pressure indicated has been less.

5. In one case the C line was seen long and unbroken, while the yellow line was equally long, but broken.

The circumstance that this line is so rarely seen dark upon the sun makes me suspect a connection between it and the line at 5015 Angström, which is also a bright line, and often is seen bright in the chromosphere, and then higher than the sodium and magnesium lines, when they are visible at the same time; and the question arises, must we not attribute these lines to a substance which exists at a higher temperature than those mixed with it, and to one of very great levity? for its absorption-line remains invisible, as a rule, in spot-spectra.

I have been able to make a series of observations on the fine spot which was visible when I commenced them on April 10th, not far from the centre of its path over the disc. At this time, the spot, as I judged by the almost entire absence of indications of general absorption in the penumbral regions, was shallow, and this has happened to many of the spots seen lately. A few hours' observation showed that it was getting deeper apparently, and that the umbræ were enlarging and increasing in number, as if a general down-sinking were taking place; but clouds came over, and the observations were interrupted.

By the next day (April 11) the spot had certainly developed, and now there was a magnificently bright prominence, completely over the darkest mass of umbra, the prominence being fed from the penumbra or very close to it, a fact indicated by greater brilliancy than in the bright C and F lines.

April 12. The prominence was persistent.

April 15. Spot nearing the limb, prominence still persistent over spot. At eleven I saw no prominence of importance on the limb, but about an hour afterwards I was absolutely startled by a prominence not, I think, depending upon the spot I have referred to, but certainly near it, more than 2′ high, showing a tremendous motion towards the eye. There were light clouds, which reflected to me the solar spectrum, and I therefore saw the black C line at the same time. The prominence C line (on which changes of wave-length are not so well visible as in the F line) was only coincident with the absorption-line for a few seconds of arc!

Ten minutes afterwards the thickness of the line towards the right was all the indication of motion I got. In another ten minutes the bright and dark lines were coincident.

And shortly afterwards what motion there was was towards the red!

I pointed out to the Royal Society, now more than a year ago,* that the largest prominences, as seen at any one time, are not necessarily those in which either the intensest action or the most rapid change is going on. From the observations made on this and the following day, I think that we may divide prominences into two classes:—

1. Those in which great action is going on, lower vapours being injected; in the majority of cases these are not high, they last only a short time—are throbs, and are often renewed, and are not seen so frequently near the sun's poles as near the equator. They often accompany spots, but are not limited to them. These are the intensely bright prominences of the American photographs.

2. Those which are perfectly tranquil, so far as wave-length evidence goes. They are often high, are persistent, and not very bright. These do not, as a rule, accompany spots. These

* Proc. Roy. Soc. 1869, p. 354, Mar. 17.

are the "radiance" and dull prominences shown in the American photographs.

I now return to my observations of the spot. On the 16th, the last of the many umbræ was close to the limb, and the most violent action was indicated occasionally. I was working with the C line, and certainly never saw such rapid changes of wave-length before. The motion was chiefly horizontal, or nearly so, and this was probably the reason why, in spite of the great action, the prominences, three or four of which were shut out, never rose very high.

I append some drawings, made, at my request, by an artist, Mr. Holiday, who happened to be with me, and who had never seen my instrument or the solar spectrum widely dispersed before. I attach great importance to them, as they are the untrained observations of a keen judge of form.

The appearances were at times extraordinary and new to me. The hydrogen shot out rapidly, scintillating as it went, and suddenly here and there the bright line, broad and badly defined, would be pierced, as it were, by a line of intensely brilliant light parallel to the length of the spectrum, and at times the whole prominence spectrum was built up of bright lines so arranged, indicating that the prominence itself was built up of single discharges, shot out from the region near the limb with a velocity sometimes amounting to 100 miles a second. After this had gone on for a time, the prominence mounted, and the cyclonic motion became evident; for away from the sun, as shown in my sketch, the separate masses were travelling away from the eye; then gradually a background of less luminous hydrogen was formed, moving with various velocities, and on this background the separate "bombs" appeared (I was working with a vertical spectrum) like exquisitely jewelled ear-rings.

It soon became evident that the region of the chromosphere just behind that in which the prominence arose, was being driven back with a velocity something like twenty miles a second, the back-rush being so local that, with the small image I am unfortunately compelled to use, both the moving and rigid portions were included in the thickness of the slit. I saw the two absorption-lines overlap.

These observations were of great importance to me; for the rapid action enabled me to put together several phenomena I was perfectly familiar with separately, and see their connected meaning.

They may be summarised as follows, and it will be seen that they teach us much concerning the nature of prominences. When the air is perfectly tranquil in the neighbourhood of a large spot, or, indeed, generally in any part of the disc, we see absorption-lines running along the whole length of the spectrum, crossing the Frauenhofer lines, and they vary in depth of shade and breadth according as we have pore, corrugation, or spot under the corresponding part of the slit—a pore, in fact, is a spot. Here and there, where the spectrum is brightest (where a bright point of facula is under the slit) we suddenly see this appearance—an interesting bright lozenge of light. This I take to be due to bright hydrogen at a greater pressure than ordinary, and this then is the reason of the intensely bright points seen in ranges of faculæ observed near the limb.

The appearance of this lozenge in the spectroscope, which indicates a diminution of pressure round its central portion, is the signal for some, and often all, of the following phenomena:—

1. A thinning and strange variation in the visibility and thickness of the hydrogen absorption-line under observation.

2. The appearance of other lozenges in the same locality.

3. The more or less decided formation of a bright prominence on the disk.

4. If near the limb, this prominence may extend beyond it, and its motion-form will then become more easy of observation. In such cases the motion is cyclonic in the majority of cases, and generally very rapid, and—another feature of a solar storm—the photospheric vapours are torn up with the intensely bright hydrogen, the number of bright lines visible determining the depth from which the vapours are torn, and varying almost directly with the amount of motion indicated.

Here, then, we have, I think, the chain that connects the prominences with the brighter points of the faculæ.

These lozenge-shaped appearances, which were observed close to the spot on the 16th, were accompanied by the "throbs" of the eruption, to which I have before referred; while Mr. Holiday was with me—a space of two hours—there were two outbursts, separated by a space of almost rest, and each outburst consisting of a series of discharges, as I have shown. I subsequently witnessed a third outburst. The phenomena observed on all three were the same in kind.

On this day I was so anxious to watch the various motion-forms of the hydrogen-lines, that I did not use the tangential slit. This I did the next day (the 17th of April) in the same region, when similar eruptions were visible, though the spot was no longer visible.

Judge of my surprise and delight, when upon sweeping along the spectrum, I found HUNDREDS of the Frauenhofer lines beautifully bright at the base of the prominence!!!

The complication of the chromosphere spectrum was greatest in the regions more refrangible than C, from E to long past *b*, and near F, and high pressure iron vapour was one of the chief causes of the phenomenon.

I have before stated to the Royal Society that I have seen the chromosphere full of lines; but the fulness then was as emptiness compared with the observation to which I now refer.

A more convincing proof of the theory of the solar constitution, put forward by Dr. Frankland and myself, could scarcely have been furnished. This observation not only endorses all my former work in this direction, but it tends to show the shallowness of the region on which many of the more important solar phenomena take place, as well as its exact locality.

The appearance of the F line, with a tangential slit at the base of the prominence, included two of the lozenge-shaped brilliant spots to which I have before referred; they were more elongated than usual—an effect of pressure, I hold, greater pressure and therefore greater complication of the chromosphere spectrum; this complication is almost impossible of observation on the disc.

It is noteworthy that in another prominence, on the same side of the sun, although the action was great, the erupted materials were simple, *i.e.*, only sodium and magnesium, and that a moderate alteration of wave-length in these vapours was obvious. Besides these observations on the 17th, I also availed myself of the pureness of the air to examine telescopically the two spots on the disc, which the spectroscope reported tranquil as to up and down rushes. I saw every cloud-dome in their neighbourhood perfectly, and I saw these domes drawn out, by horizontal currents, doubtless, in the penumbræ, while on the floors of the spots, here and there, were similar cloud-masses, the distribution of which varied from time to time, the spectrum of these masses resembling that of their fellows on the general surface of the sun.

I have before stated that the region of a spot comprised by the penumbræ appears to be shallower in the spots I have observed lately (we are now nearing the maximum period of sun spots); I have further to remark that I have evidence that the chromosphere is also shallower than it was in 1868.

I am now making special observations on these two points, as I consider that many important conclusions may be drawn from them.

Zoological Society, May 26.—G. R. Waterhouse, V.P., in the chair. A letter was read from Mr. W. H. Hudson, C.M.Z.S., containing remarks on birds observed in and around Buenos Ayres, being the fourth communication received from this gentleman on the same subject.—Mr. R. B. Sharpe exhibited and made remarks on a specimen of a rare Asiatic bird, *Podoces panderi*, from the collection of Lord Lilford.—Professor Owen read the sixteenth of a series of memoirs on *Dinornis*, containing an account of the trachea and of some other internal organs of certain species of this genus, together with a description of the brain and some nerves and muscles of the head of *Apteryx australis*.—Dr. J. Murie read a paper on the anatomy of the Prongbuck (*Antilocapra americana*), founded on the examination of the specimen of this animal which had died in the Society's Gardens in the year 1867.—A communication was read from Dr. A. B. Meyer, containing remarks on the poisonous glands of the snakes of the genus *Callophis*, being supplementary to his paper on the same subject published in the *Monatsberichte* of the Academy of Berlin.—A communication was read from Surgeon Francis Day, F.Z.S., containing notes on some fishes from the western coast of India, amongst which were several species described as new to science.—Mr. H. Adams communicated the descriptions of some new species of land and fresh-water shells obtained by Mr. E. Bartlett in Eastern Peru, and by Mr. R. Swinhoe in China and Formosa. Mr. Adams also described two new species of land shells from Africa.

Aeronautical Society, June 3.—Mr. James Glaisher, F.R.S., in the chair. Several papers were read and illustrated by models. An instrument for ascertaining the connection between velocity and pressure, exhibited by Dr. Smyth, of Maidstone, procured the encomiums of the chairman, who stated that it was calculated to supply information that was wanting in the instrument which he had been using. In the course of discussion, Mr. A. Stewart Harrison strongly advocated the necessity of an experimental fund, whereupon the chairman asked Mr. Fred. W. Brearey, the honorary secretary, to read the minutes of a late council meeting at Stafford House, at which were present Mr. Glaisher (in the chair), Sir William Fairbairn, Bart., Mr. Brook, Mr. Wright, Mr. Wenham, Mr. Oheen, and Mr. Brearey; as follows:—Sir William Fairbairn observed that we know but little of the re-action or lifting power of various forms of screw blades in the atmosphere relative to the force employed, though such experiments might be easily tried and the data obtained. Mr. Brook was of opinion that if a successful aerial machine was to be constructed, the most simple and obvious plan was that of inclined surfaces impelled forward horizontally. The most successful experiment that he had ever witnessed was upon this principle, the motive power being a wound-up clock spring, which, as long as the power lasted, sustained the machine, and further that most large birds were capable during long periods of their flight of sustaining themselves exactly in this way. It was further remarked that we were practically ignorant of the correct laws of the sustaining power of inclined surfaces of different forms and areas, and this want of knowledge was a perpetual stumblingblock to those who were wishing to spend time and money on experiments. From the fact that, as the weight and size of birds increased, so did the relative wing area decrease, it would appear that the ratio of sustaining surface to weight or resistance was by no means in equal proportion. The Chairman stated that with respect to plane surfaces of various figures exposed to the direct impact of the wind, he had already been trying some experiments with such instruments as were at his disposal, and that by employing two anemometers at the same time, so as to be sure of comparative results, he found that the indication of force increased with the size of the surface; also in the two instruments, equal surfaces shaped into different contours gave different results. These interesting experiments, so directly bearing upon the question of aerial propulsion and resistance, were still occupying his attention; but at present he could tell us nothing from actual experiment of the resistance of inclined surfaces of various forms. It was then proposed that an experimental fund should be raised by subscription, and that a suitable and well finished anemometer should be constructed, having the means of instantly setting various plane surfaces at any desired angle, and capable of registering both horizontal and vertical force simultaneously for all degrees of inclination. The results to be published for the benefit of the Society." Upon this proposition being put to the meeting, it was carried unanimously.

Ethnological Society, June 1.—Special Sectional Meeting at the Royal United Service Institute. Prof. Huxley, F.R.S. president, in the chair.—A letter was read from Lieut. Oliver, relative to the recent destruction of a cromlech in Jersey.—Col. Lane Fox read communications from Dr. Caulfield, "On the discovery of copper celts near Buttevant, Co. Cork;" and on a supposed Ogham inscription from Rus-glass, Co. Cork.—Mr. C. Spence Bate, F.R.S., then presented an elaborate "Report on the prehistoric antiquities of Dartmoor," forming one of the series of reports being now collected by the Society, with a view to obtaining accurate information on the present condition of the megalithic monuments of this country. After noticing the physical features of the district, the author described in detail the numerous stone circles, avenues, menhirs, cromlechs, cairns, and other prehistoric monuments of Dartmoor. He suggested the idea that the stones in some of the avenues may have been erected in commemoration of the death of persons of distinction, one being added for each burial. The depressions on the summit of some of the cairns were regarded rather as indications of unfinished work than of subsequent disturbance by treasure-seekers. Evidence was adduced of the wanton destruction of the granite blocks in some of the cromlechs; and both in the paper and in the subsequent discussion attention was forcibly directed to the importance of obtaining legislative protection to these prehistoric monuments. A large series of diagrams, plans, coloured sketches, photographs, and specimens illustrated this valuable communication. The discussion was sustained by Mr. W. Morrison, M.P., Mr. Moggridge, Mr. Hyde Clarke, Mr. Black, Rev. G. St.-Clair, Dr. Campbell, and Mr. Lewis.

Chemical Society, June 2.—Prof. Williamson, F.R.S., president, in the chair. Mr. W. B. Tustin was elected a Fellow. —Prof. Odling, F.R.S., delivered a lecture "On the Platinum Ammonia compounds." Platinum combines with chlorine in two proportions, viz., with four atoms of chlorine to form platinic chloride, $Pt\ Cl_4$, and with two atoms of chlorine to form platinous chloride, $Pt\ Cl_2$. All the platinum ammonia compounds are produced in first instance from the plantinous chloride, none of them directly from the platinic chloride. If this is borne in mind, a great simplicity will at once be introduced into the study of the platinum ammonias. Next, the lecturer proceeded to show the manifestations of the atomicities of nitrogen, boron, silicon, and platinum as illustrated in the compounds $NH_3\ HCl$, $BF_3\ KF$, $SiF_4\ K_2\ F_2$, and $Pt\ Cl_4\ K_2Cl_2$, which four compounds are decidedly analogous, and deduced from this as well as from many other evidences the necessity of writing the formula of sal-ammoniac $NH_3\ HCl$, and not $NH_4\ Cl$. Having established this, the metallic derivatives of sal-ammoniac were ranged into two sets—those in which the metal can be detected by the usual tests, and those in which this cannot be done; the first may be typified by the formula NH_3 m Cl, the second by NH_2 m HCl. [The small letter indicates that quantity of a metal which occupies the place of one atom of hydrogen.] The lecturer then extended his comparison of the manifestations of the pentad nature or the pendacity of nitrogen with those of the tetradicity of carbon, and concluded this kind of preface by reminding of the necessity of studying mineral chemistry in the light of organic chemistry. He then gave a short history of the platinum ammonia compounds, beginning with the so-called green salt of Magnus discovered in 1828, mentioning the salts prepared and described by Gros, Reiset, Peyronne, and others, and finally by stating Laurent and Gerhardt's latest arrangements for classifying these compounds. That classification is now by no means satisfactory, and Dr. Odling hopes to bring forward at some future meeting his own views on this subject.

Anthropological Society, May 31.—Dr. R. S. Charnock, vice-president, in the chair. Mr. George Thorne Ricketts, Her Majesty's consul, Manila, was elected a Fellow.

A paper by Dr. John Shortt was read on "The Armenians of Southern India." Early in the sixteenth century a few Armenians found their way into Southern India with the countenance and support of the Hon. East India Company, and under a contract with the company equal privileges with British subjects were conceded to the Armenians. The company further extended favours to them when they reached, in any town, the number of forty, by the provision of a place of worship, and by annual grants of money. For a long time after their arrival in India they avoided mingling with other people, but latterly that rule has been broken through, and alliances in marriage with Europeans are not unfrequent. The Armenians have diminished in numbers, and, it is said, are daily decreasing in influence. The chief causes of their approaching extinction in India appear to be the vice of intemperance, the taint of disease, and the contact with Europeans, more especially the English. The physical and moral characteristics were described; in the former it was stated that the Armenians are strongly allied to the Jewish race, from which they claim descent.

A paper by Mr. John Stirling, M.A., was read on "The Races of Morocco." The inhabitants of that part of Barbary known as Morocco may be arranged under the following heads, viz., Berbers, Al-Ryf, Arabs, Bohára troops, and other Negroes or half-breeds, and Jews. The word *Kabyles* often erroneously used to designate some North African race, is a term applied by the Moors to distinguish villagers or country people engaged in agriculture. The Berbers are probably of Phœnician blood mixed with an old race indigenous to Morocco; at any rate, the remains of dolmens and other monuments would point to that origin. The Al-Ryf are wild descendants of the Ryf pirates, the inhabitants of the northern spurs of the Atlas range which separates Morocco from Algeria. The Al-Ryf are comparatively a fair people, and such of them as follow in-door occupations exhibit a delicate olive complexion. The Bohára troop form a remarkable race; their ancestors were a rebellious Negro tribe living south of the Atlas. They have married with Moorish women, but still retain to a great degree the Negro aspect. The Negroes of Morocco have intermarried with the fair Moors, and produced a mixed race. The true Moors are fair, some individuals having blue eyes and light or red hair.

Sir Duncan Gibb, Bart., M.D., in a paper "On the Paucity of Aboriginal Monuments in Canada," attributed the absence in

Canada of monuments built of stone to the peculiar character of the climate, which would be unfavourable to their preservation. He anticipated the discovery some day of traces of the ancient inhabitants in the great caverns north of Flamborough, and in the island of Anticosti.

Institution of Civil Engineers, May 17.—Charles B. Vignoles, F.R.S., president, in the chair. The paper read was "On recent improvements in regenerative hot-blast stoves for blast furnaces," by Mr. E. A. Cowper, M. Inst. C.E. The author stated that when, in 1828, the late Mr. J. B. Neilson, M. Inst. C.E., introduced the plan of heating the air employed as blast, by means of iron pipes placed in or near a fire, the increase of temperature was at first only from 60° to 100° Fahr. Subsequently, Mr. Neilson obtained a temperature of 600° or 650° and the pipe stoves had since been urged up to 900°, and in a few cases to 1·00°. The wear and tear, however, with such temperatures of blast were considerable; there was great loss of heat by conduction, and the pipe stoves were, as a rule, worked in a leaky condition, necessitating the expenditure of engine power for blowing air uselessly. The improvements described in the paper were based upon Mr. Siemens' regenerative furnace. Each stove of a pair consisted of a wrought-iron cylindrical casing, lined with fire-brick, and provided with a central shaft or flue, which extended to within a few feet of the brick dome forming the top. Around this shaft there were a number of compartments, or boxes, formed of bricks so placed that those in one course were not exactly coincident in position with those in the courses either above or below, though a passage was left open from the bottom to the top of the mass of brickwork. This wrought-iron casing was provided with several valves, three being for the cold blast, of gas, and of air for combustion, and two being for the exit of the hot blast and of the products of combustion. When a stove had been at work heating blast, and it was wanted to reheat it, the first thing to be done was to put another stove in operation, then to shut the hot and the cold blast valves, allowing the air in the stove to be blown out at a small valve to reduce it to atmospheric pressure. The gas, air, and chimney valves were next opened, and the gas, igniting as it entered, gave a large volume of flame right up the central shaft and over and into the regenerator, thus heating the top course of brickwork considerably, the next course rather less, and so on, the products of combustion passing away to the chimney at a temperature of about 300°. In the course of a few hours a large amount of caloric was stored up in the bricks forming the regenerator, a good red heat penetrating nearly to the bottom, when the stove was again ready to heat the blast to a temperature of 1,400° or 1,500°. In these stoves the cost of dust catchers was avoided, and the expense of producing gas was also saved, as the gas was used direct from the top of the blast furnace, and the stoves could be cleaned out with the greatest facility. The construction of the regenerator in compartments or boxes, connected together vertically but not horizontally, gave the power of applying the blast with efficiency (inasmuch as the whole force of the blast was confined to the one passage that was being blown at the time), and admitted of a brush being passed up or down the boxes to remove the dust. The form and proportion of the passages had been found, after numerous experiments, to produce an excellent effect in mixing the air, thereby ensuring a rapid and perfect conduction of heat from the bricks to the air, or *vice versa*, from the products of combustion to the bricks. The results obtained by Messrs. Cochrane from the adoption of these stoves at Ormesby, as regarded the quality of iron, the increased make, and the saving of coke in the blast furnace, had been most satisfactory. Thus there was a saving of 4 cwt. of coke per ton of iron produced, by the use of the regenerative stoves for heating the blast, when compared with good cast-iron pipe stoves, and the saving was still more over ordinary pipe stoves. With a large furnace, producing 475 tons a week, the first cost of these stoves was somewhat less than the cost of pipe stoves, while the expense of working was less, so that the profit, taking everything into account, was estimated to amount to about 4,162*l*. a year.

Cambridge

Philosophical Society, May 16.—Professor W. Cayley, president, in the chair. The following communications were made to the Society:—

(1.) By Mr. Sedley Taylor (Trinity). Mr. Taylor described the nature and classification of musical sounds, their laws and connection, and illustrated experimentally the subject of "beats," and explained at some length, with illustrations, Helmholtz's theory of harmony. The rest of the paper was devoted to a criticism of a theory of consonance given by Professor Tyndall in his published lectures on sound. This theory, he maintained, was, while professing to be that of Helmholtz, a totally different one, in flat contradiction to the facts of experience, and in reality wholly erroneous.

(2.) On a case of asymmetry in the human body, by Professor Humphry. The subject of this paper was a female patient in Addenhook's Hospital, at Cambridge. The asymmetry was very marked, carried out through the whole body; the right arm, for example, being more fully developed, and 2½ inches longer than the left, and extending even to the mammary glands, teeth, tonsils, &c. The subject had always enjoyed good health, was strong, and fully developed. No paralysis had ever been produced by this asymmetry, as had been the case in the instance mentioned by Van der Kolb, a cast of the brain of which was exhibited. Professor Humphry expressed himself wholly unable to account for this instance. As the person was alive and well, of course examination of the internal organs was impossible.

Paris

Academy of Sciences, June 6.—A considerable number of works and memoirs were received in candidature for various prizes in the gift of the Academy.—M. Chasles presented a note by M. Mannheim, "On the determination of the osculatory plane and radius of curvature of the trajectory of some point in a straight line, which is displaced under certain conditions;" and also a note by MM. F. Klein and S. Lie, "On a certain family of curves and surfaces."—A note was read by M. Des Cloiseaux, "On the optical properties of benzile, and of some bodies of the camphor family, in the crystallised state and in solution." The author has found that crystals of benzile rotated the plane of polarisation in different ways, and the right and left crystals, when dissolved and crystallised two or three times, likewise gave a mixture of crystals with opposite rotations. Solution of benzile in ether has no action on polarised light. Benzile thus possesses optical properties similar to those of periodate of soda. Common camphor in solution deviates the plane of polarisation, whilst its crystals have no action upon polarised light. Camphor of patchouli and mint camphor (menthole), both belonging to the hexagonal system, have a negative, uniaxial, double refraction, and their solutions in alcohol deviate the plane of polarisation to the left. Three camphors belonging to the cubic system, namely, Bornean camphor, terecamphene, and monohydrochlorate of turpentine, have no action on polarised light when crystallised, but in solution strongly deviate the plane of polarisation, the first to the right, the other two to the left.—M. Duchemin described a marine galvanic battery, set in action by contact with sea water. It consists of a thick cylinder of zinc, pierced with holes, and containing a porous vessel, enclosing a carbon element surrounded by powdered coke and perchloride of iron.—An extract of a letter from Father Secchi to M. Fizeau, "On the displacement of the lines observed in the solar spectrum," was read. M. Le Verrier communicated an extract from a letter of M. Winnecke announcing his discovery of a new telescopic comet on the night of the 29-30th May, at Carlsruhe.—Mr. H. Sainte-Claire Deville communicated a second memoir on the action of water on iron and of hydrogen on oxide of iron. In this paper he described his experiments with iron at temperatures of 150°, 265°, 440°, 860°, and 1040° C. (= 302°, 509°, 824°, 1580°, and 1904° F.) and with aqueous vapour at constant and varying tensions.—A paper was read by M. E. Frémy on the reduction of nitrous acid by metals, containing the continuation of his researches on this subject brought under the notice of the Academy on the 10th January (see NATURE, No. 12). He identified the body obtained by the reduction of nitrous acid and the nitrites with the oxy-ammonia of M. Lossen, NH^3O^2 (or NH^2O, HO) and stated that it possessed marked basic properties, and is strongly reductive.—M. de Quatrefages presented a note by M. E. Perrier on the circulation of the Oligochæta of the group Naïdæ, which he described from researches made upon *Dero obtusa*. The circulatory apparatus in this worm consists, according to the author, of a dorsal and a ventral vessel, united by a most complex vascular apparatus which varies considerably in its structure in different regions of the body.—A note by M. Feltz, on the phenomena of which the white globules of the blood, and the walls of the capillary vessels, are the seat during inflammation, was communicated by M. C. Robin.—M. R. Wolf suggested that instead of applying the decimal mode of division to the quadrant of the circle and the quarter of the day, as proposed by M. D'Abbadie, the whole circle and the whole day should be taken as the unit of division. M. D'Abbadie remarked that the quadrant is the natural unit which has always been adopted for trigonometrical purposes, and indicated some practical inconveniences which would result from a change. Of the remaining communications only the titles are given.

BOSTON

Natural History Society, *Section of Microscopy*, Feb. 9.—Dr. B. Joy Jeffries in the chair. The following paper was read:—"Notes on Diatomaceæ," by Professor Arthur Mead Edwards. "A few days since (Sept. 1869) I made a gathering in a ditch communicating with the salt water of the Hudson River, opposite the city of New York, at Weehawken, N. J. Of course the water in the ditch was salt, and, in fact, in it last spring I had caught specimens of Stickleback (*Gasterosteus*) which had come up there from the river to spawn, as is their wont to do. The Ten-spined Stickleback (*G. pungitius*) I had found very plentiful, and mixed with it a few individuals of the Three-spined (*G. aculeatus*); in fact these fish occurred in such numbers that when the water became foul, as it did by evaporation, the bottom of the ditch was literally covered with their dead bodies. The gathering, however, I have to speak of at the present time was made for the purpose of procuring Diatomaceæ, and consisted of specimens of an alga belonging to the genus *Enteromorpha*, having attached to it more or less firmly numerous Diatomaceæ and animals. The commonest form of Diatom was a *Cyclotella*, and seemingly fixed in some manner to the *Enteromorpha*, for it was not shaken off by pretty rough usage. How it was fixed I could not detect; most likely by means of a mucous envelope of such tenuity that it is not readily seen. The next most common form is the truly wonderful, inexplicable *Bacillaria paradoxa*, the paradoxical bundle of sticks. Often and often have I spent hours looking at this marvel of nature; the motion without apparent cause or mode, an invisible joint which, as a friend of mine, an engineer, once remarked, would be a fortune to any one who would discover it, for here we have several sticks forming the bundle, moving over each other without separating, and yet the use of the highest powers of the microscope has failed to detect the means of their union into one mass or composite group of individuals. This grouping of individuals together, which we so commonly find among the Diatomaceæ, as in *Schizonema*, *Achnanthes*, *Melosira*, and a host of other genera, appears to me to have its analogue in the animal kingdom in the Polyzoa; which, although generally fixed, yet at certain periods throw off motile forms by means of which the species is distributed. Do not the Diatomaceæ do likewise? I am of opinion that they do, and I shall produce evidence on that point further on. As to the *Bacillaria paradoxa*, the oftener I watch it the more it puzzles me. Not long since I saw one specimen (of course I mean one bundle of individuals) slide out to its utmost limit across the field of view, and then, becoming entangled with two others, which likewise were made up of many individuals, some eight or ten of its frustules (as the complete individuals are called) were twisted around almost off from the rest, so as to lie at right angles to them, and when the group containing the largest number of frustules receded to their former position, which they soon did, the eight or ten seeming by the act of twisting to lose their power of motion among themselves for the time being, were dragged along in a helpless condition, and twisted completely around one revolution, so as thereafter to fall back again into their places, when all went on as usual. That is to say, the regular motion of all the frustules over each other succeeded. Now what kind of a joint can it be that permits of such eccentric movement? As I have already said, I am more puzzled than ever. Along with the *Bacillaria* in the brackish water at Hoboken, I found numerous individuals of an *Amphora*, which I have known in this neighbourhood for many years, and which I considered unnamed as yet. To it I have given the provisional name of *A. lanceolata*, on account of the form of its outline. This genus has always been considered an epiphytaceous one; that is to say, one which grows attached to other plants or submerged substances, yet this form was free and in active motion. In fact I think it was one of the most lively Diatoms I ever saw. So another small species of *Amphora* which is common near here, is always, as far as I have noticed, free. Here we have species appearing both in the free and attached conditions, and this is even more strikingly illustrated in *Schizonema*. *Bacillaria paradoxa* is usually set down as the most rapid in motion of the Diatomaceæ, its velocity being recorded by Smith, as he measured it, at over one two-hundredth of an inch in a second. This is certainly pretty quick when we consider that the length of the frustule is only ·0025 of an inch. But my experience has been that its velocity varies in every degree from that mentioned to perfect rest; at times some individuals will be in rapid movement, while others are motionless; and also I have remarked that from sunrise to noon seems to be the period during which, under ordinary conditions, the movement is most active, while during the afternoon it is very sluggish, and at night almost *nil*. This *Amphora*, as I saw it at the time mentioned, was moving even more rapidly than I ever saw a *Bacillaria* move, and that with a steady onward progression very different from that of most naviculiform diatoms. Many months since I mentioned at one of the meetings of the Lyceum of Natural History in New York, that I had seen two apparently different genera of Diatoms existing within the same investing tube; and now I wish to place that fact upon record, and to state one or two more instances of the same mode of growth. During the month of March 1868, I found in the harbour of New York specimens of *Schizonema Grevillei* in active motion within their investing tubes, but accompanied by a much smaller form possessing a totally different outline from *S. Grevillei*, being blunter at the ends, and with parallel sides. During the same month, and also in April, I found this mode of occurrence very common, and also *Schizonema Grevillei* and a *Homœocladia* in the same tube, and *Schizonema cruciger* and the small form mentioned above, both in the same tube, and *S. cruciger* and *Grevillei* in the same tube. In all these cases the frustules were in lively motion, passing over each other from one end to the other of the tube. In May of the present year, 1869, I found growing in the salt water of the 'Mill pond' at Salem, Mass., *Schizonema cruciger* and *Nitzschia closterium*, W. S. (*Ceratoneis closterium*, C. G. E., and *Nitzschiella closterium*, L. R.), both in the same tube. And here it will be necessary to say something in regard to the form I have called *Nitzschia closterium*, as I shall thereby, I hope, be enabled to clear away a little fog of synonyms. Neither Smith, Kützing, nor Rabenhorst describes or figures any species living within a tube like *Schizonema*, the frustules of which have an outline and markings similar to *Nitzschia closterium*, so that it is not likely that they ever saw anything but the free form or condition of this species. However, Ehrenberg figures and describes, under the designation of *Schizonema? Agardhii* (*Die Infusionsthierchen*, 1838, p. 343, t. xx. fig. xvi.), a form agreeing with this, but the structure of the frustule is that of *Nitzschiella* of Rabenhorst, so that the specific name of this species should be *Agardhii*, whatever its genus be decided to be hereafter."

March 2.—Dr. C. T. Jackson, vice-president, in the chair. The following papers were presented:—"Description of the Larva and Chrysalis of *Papilio Rutulus* Boisd., of California," by Samuel H. Scudder.—"On the Phosphate Beds of South Carolina," by N. S. Shaler. The latter contains a partial account of the observations made upon this district by the author, while in the employ of the United States Coast Survey, and is published with the permission of the Superintendent of the Survey, Prof. Benj. Pierce, of Cambridge. A portion of the conclusions have a certain commercial as well as scientific value, and it was deemed by the Superintendent desirable to place them before the public at the earliest opportunity. The remainder of the description of these beds will be found in the report of the work of the Coast Survey for 1870.

March 16.—Mr. William T. Brigham in the chair. The following papers were presented:—"Note on the Occurrence of *Euleptorhamphus longirostris* on the Coast of Massachusetts," by F. W. Putnam.—"Revision of the Classification of the Mollusca of Massachusetts," by W. H. Dall, Smithsonian Institution.

NEW YORK

Lyceum of Natural History, *Chemical Section*, May 9.—Prof. Charles A. Seely "On the Constitution of Ammoniacal Amalgam." Ammonium amalgam was discovered by Berzelius in 1808; and immediately after by Pontin, Seebeck, and Trommsdorff. Its easy preparation, singular properties, and its relation to current theories, have made it familiar to all chemists. It led to the adoption of Ampere's ammonium theory, gave a great impetus to the theory of organic radicals, and revived the notions of the alchemists of the compound nature of metals. Early in this century it led many to conclude that the base of nitrogen is a metal; and at the present time, without doubt, has assisted in giving currency to the notion that hydrogen is a metal. Except for it, perhaps the crudity, hydrogenium, would not have been inflicted upon us. Of course it has occupied a conspicuous place in chemical literature; scoresof papers, and at least two books, have been printed about it. The name ammonium amalgam expresses the supposed constitution of the substance; the radical ammonium is represented as dissolved in or united with mercury. The ammonium is, moreover, conceded to be a solid or a liquid, and to have a truly metallic character. Thus the latest and best authorities present the case. It is described, in nearly all treatises on chemistry, as if its constitution was as certainly ascertained as that of common salt. There have been from the beginning, however, those who doubted the prevailing ideas, and some (see Daniel's "Chemical Philosophy," p. 520, and Dr. Wetherill on Ammonium Amalgam, in *Silliman's Journal*, vol. x., p. 160) boldly objected to them, but the reasons they alleged had not sufficient weight. Ammonium amalgam has always been a pet with chemists; it has always been ready for the service of one theory or another. The ammonium theory, the radical theory, the nitrogen and hydrogenium theories, have each in their turn been of too much importance to permit any of their props to be withdrawn.

The author considers the so-called ammonium amalgam to be a mechanical or physical mixture of liquid mercury with the gases ammonia and hydrogen, and that its semi-solid consistence is due to the mixture having the nature of a froth. When sodium-amalgam is brought into a solution of sal-ammoniac (the ordinary method of preparing ammonium amalgam) the chlorine combines with the sodium, and the residue ($NH_3 + H$) of the sal-ammoniac is set free all over the surface of the mercury. The particles of the mixed gases adhere to the mercury, and by reason of the movement bringing to the surface fresh mercury, they become enfilmed and carried inward, until the mixture becomes a homogeneous froth. The principal considerations by which this view of the constitution of ammonium amalgam has been reached, are as follows:—

1. The volume of ammonium amalgam is inexplicable in any other way; it is utterly inconsistent with the well-established laws of combinations by volume. There is no case of a liquid or solid chemical compound, or amalgam, which has any analogy to it.

2. Mercury has a mirror-like surface, while ammonium amalgam has comparatively a whiter and more dead surface; it approaches in appearance to matt silver. Such changes are characteristic of froths.

3. If ammonium amalgam be subjected to varying pressure, its volume changes apparently in accordance with Mariotte's law of gaseous volume. To illustrate this important fact, a glass tube one-third inch in diameter, twenty inches long, and fitted with a plunger, was employed. Mercury containing a little sodium was poured into the tube to one-third of an inch in depth, and upon this was poured a strong solution of chloride of ammonium, occupying about two inches in length of the tube. The ammonium amalgam was completely formed in a few minutes, and occupied several inches of the tube. On adjusting and depressing the plunger, the volume of the amalgam progressively diminished till it closely approached the original volume of the amalgam. Also it was notable that the amalgam progressively gained fluidity and the mirror surface, till at the greatest pressure it appeared like mercury. On withdrawing the pressure the original volume and appearance of the compound were resumed, and on reducing the pressure below that of the air, the amalgam still expanded, until it rose above the surface of the liquid in the tube. If the great pressure be maintained, more ammonium amalgam will be formed, the mass expanding progressively, apparently in accordance with the fact that the absorption or adhesion of gases to liquids is favoured by pressure. By means of the simple apparatus used a pressure of ten atmospheres, or a good vacuum, is easily and at once attainable, and the experiments with it are very striking.

The so-called ammonium amalgam is therefore not an amalgam at all; ammonium is not proved to be a metal, and if it be admitted that the monatomic radical really exists in ammonium amalgam, it is neither a solid nor a liquid, but a gas.

The considerations regarding ammonium amalgam are evidently equally applicable to Loew's hydrogenium amalgam; both are only metallic froths. The expansion of palladium observed by Graham, on its absorption of hydrogen, is probably analogous to the case in question. In both cases the gases concerned are condensed by reason of their attraction to the metal; and if the molecules of palladium were made free to move, as those of mercury, it is probable that Graham's hydrogenium alloy would become a palladic froth, more remarkable than the corresponding mercuric froth. Many have erroneously supposed that hydrogen was conspicuous in its capability of being absorbed by metals, and thus have more readily been infused with the hydrogenium theory. Oxygen has an eminence over hydrogen in that property, and yet no one has a theory of oxygenium. Iron absorbs carbonic oxide, but no one is bold enough to suggest that carbonic oxide is a metal.

DIARY

THURSDAY, JUNE 16.

ROYAL SOCIETY, at 8.30.—Papers to be read by Dr. Hofmann, F.R.S.: Dr. H. E. Armstrong, Dr. Alex. Rattray, Prof. Macalister, C. Tomlinson, F.R.S., W. Huggins, F.R.S., Sir Edward Sabine, P.R.S., the Earl of Rosse, F.R.S., Dr. Stenhouse, F.R.S., G. Busk, F.R.S., the Hon. J. W. Strutt, Mr. J. Broughton, Mr. A. Le Sueur, and W. H. L. Russell, F.R.S.

ROYAL SOCIETY OF ANTIQUARIES, at 8.30.—On Heydon Church, Yorkshire: Mr. G. E. Street.

LINNEAN SOCIETY, at 8.—On two Species of Serapias which occasionally present semi-labelliform lateral sepals: Mr. J. T. Moggridge.

CHEMICAL SOCIETY, at 8.

NUMISMATIC SOCIETY, at 7.—Anniversary Meeting.

SUNDAY, JUNE 19.

SUNDAY LECTURE SOCIETY, at 8.—On Volcanoes: Mr. D. Forbes.

MONDAY, JUNE 20.

LONDON INSTITUTION, at 4.—Botany: Prof. Bentley.

TUESDAY, JUNE 21.

STATISTICAL SOCIETY, at 8.—On Free Libraries: Mr. W. E. A. Axon.

ETHNOLOGICAL SOCIETY, at 8.30 (at the Royal United Service Institution, Whitehall Yard).—On the Aymara Indians of Bolivia and Peru: Mr. D. Forbes.

WEDNESDAY, JUNE 22.

GEOLOGICAL SOCIETY, at 8.

THURSDAY, JUNE 23.

ZOOLOGICAL SOCIETY, at 8.30.—On the Walrus: Dr. J. MURIE.—Catalogue of the Mammals of South China and Formosa: Mr. R. SWINHOE.—On a Collection of Birds from the Island of Trinidad: Dr. O. FINSCH.

THURSDAY, JUNE 23, 1870

THE UNIT OF LENGTH

THE battle of the Standards is over, and we may say the Metre has gained the victory. The need of a new system of weights and measures to amend the strange diversities which disfigure our practice being admitted, the question has once more been started—Should we once for all found our system on a natural basis? The pendulum vibrating seconds in a certain latitude, was long ago proposed as a universal basis of linear measure, and the House of Commons somewhat countenanced it years ago, by prescribing that the length of the yard shall be determined by the length of the second's pendulum. But the action of gravitation on which the terms of the vibration depends, is subject to so many variations and disturbances, that the quantity sought cannot, even on the same spot, be absolutely the same at all times. The real length of a normal pendulum is almost unattainable, so limited is our knowledge of the force of gravity on land and at sea. A more certain basis for a natural unit has been found in the polar axis, the length of which, according to Sir John Herschel, bears a close relation to our imperial inch, and has the advantage of avoiding the many causes of error resulting from the physical peculiarities of the countries through which any measured arc may happen to pass. But are our physicists agreed as to the real length of the polar axis, and would it be worth while to make any alteration in our weights and measures for the sole purpose of attaining some scientific correspondence between the unit in use and a unit founded on nature?

The advocates of the metre rest their arguments on a much broader basis. They do not assert that the metre is absolutely and mathematically the ten millionth part of the quadrant of the earth; they know that the meridians of places differing in longitude are not all precisely of the same length; and they admit that were we now to make a new measurement with our better instruments and more extended information, we might attain much greater accuracy than was arrived at by the French philosophers at the end of the eighteenth century. What commends the metre above any other unit, is the fact, that it is already a cosmopolitan unit, widely recognised, and in general use among many nations; and that whilst other units remain as philosophical abstractions, the metre is the basis of a system, not only perfectly complete, homogeneous, and scientific, but simple and practical in all its parts. Any slight error in the determination of the metre, is more than counterbalanced by the extreme simplicity, symmetry, and convenience of the metric system; and not the least of its recommendations are, that the unit of linear measure applied to matter in its three forms of extension, viz., length, breadth, and thickness, is the standard of all measures of length, surface, and solidity; and that the cubic contents of the linear measure in distilled water at a temperature of great contraction, furnish at once the standard weight and measure of capacity.

When we said that the battle of the Standards is over and that the Metre has gained the victory, it was meant that, for practical purposes, all opposition to the introduction of the metric system has been abandoned, and that Parliament and the Government are now left to introduce it in such a way and at such a time as may be found at once practicable and satisfactory. The use of the metric system has been legalised for the last half-dozen years, but it was not till quite lately that the whole question was submitted to the calm deliberation of a Royal Commission. The Standard Commissioners, who included among their members the Astronomer Royal, the President of the Royal Society, and the late Master of the Mint, considered the question of the introduction of metric weights and measures, in any form, *ab initio*. And after careful examination they gave their verdict in its favour in the following terms:—

"Considering the information which has been laid before the Commission,—

"Of the great increase during late years of internationa communication, especially in relation to trade and commerce;

"Of the general adoption of the metric system of weights and measures in many countries, both in Europe and other parts of the world, and more recently in the North German Confederation and in the United States of America;

"Of the progress of public opinion in this country in favour of the metric system as a uniform international system of weights and measures;

"And of the increasing use of the metric system in scientific researches and in the practice of accurate chemistry and engineering construction;

"We are of opinion that the time has now arrived when the law should provide, and facilities be afforded by the Government, for the introduction and use of metric weights and measures in the United Kingdom."

The Commissioners further recommended that metric standards, accurately verified in relation to the primary metric standards at Paris, should be legalised; that verified copies of the official metric standards should be provided by the local authorities for inspectors of such districts as may require them; and that the French nomenclature, as well as the decimal scale of the metric system, should be introduced in this country. The Commissioners, whatever might have been their predilections, could not resist the fact that the civilised world pronounced itself for the metre, and they sanctioned its legalisation. What is to be regretted is that they stopped there. Since the complete substitution of the metric for the present practice is now practically certain, would it not be much better to prepare for the change and carry it into effect as speedily as possible? No advantage can come from a policy of indecision, and we trust that the Legislature may adopt a more definite course than the one sketched out by the Royal Commissioners. Let it not be imagined that the people will give themselves the trouble of learning the new system, however beautiful and easy, so long as its use is not absolutely necessary. With all the desire of the teachers to introduce it in the schools, they find that they cannot teach the old and the new tables. They cannot afford the time. A compulsory measure is the only method of dealing with the question.

The Warden of the Standards being now employed in procuring Metric Standards, it may be well to add that the mode of constructing them, either from the original Metre at the Archives, or from the copy at the Conservatoire des Arts et Métiers, has been much debated. The

International Statistical Congress, held at Berlin, decided "That the care of preparing and putting into execution the regulations to be followed in the construction of the standards, and of the system itself, should be entrusted to an International Commission, which will also see to the correction of the small scientific defects of the system." The International Geodesical Conference held at Berlin in 1867 decided: "In order to define the common unit of measures for all the countries of Europe, and for all times, with as much exactness as possible, the Conference recommends the construction of a new prototype European Metre. The length of this European Metre should differ as little as possible from that of the Metre of the Archives in Paris, and should in all cases be compared with the greatest exactness. In the construction of the new prototype standard, care should be taken to secure the facility and exactness of the necessary comparisons." And "the construction of the new prototype metre, as well as the preparation of the copies destined for different countries, should be confided to an International Commission, in which the States interested should be represented." Since then, the Imperial Academy of Science of St. Petersburg has taken the matter in hand, and a committee of the Physico-Mathematical class, consisting of MM. Struve, Wild, and Jacobi, has made a report on the subject, observing that the standard metric weights and measures of the various countries of Europe and of the United States differ by sensible though small quantities from one another. They expressed their opinion that the continuation of these errors would be highly prejudicial to science. They believed that the injurious effects could not be guarded against by private labour, however meritorious, and they recommended that an International Commission should be appointed by the countries interested to deal with the matter. This suggestion was approved by the French Government, and consequently the Conference will take place in Paris in August next, when the Astronomer Royal, Professor William H. Miller, and the Warden of the Standards, will represent this country. Everything seems thus tending towards the early realisation of the great scheme of uniformity of weights and measures throughout the world.

MUSEUMS OF NATURAL HISTORY

THERE is no doubt of the popularity of museums of natural history with the lower classes. That it is otherwise with more educated people is perhaps attributable, not so much to indifference to scientific knowledge, as to the fact that hardly any scientific knowledge is to be gained by a cursory inspection of crowded collections, arranged with reference to economy of space rather than to the existing conditions of zoological science. It must not be forgotten that the sentiment of mere wonder, which the stranger forms of animal life are so calculated to excite, was satisfied, or at least blunted, in early childhood, in the case of those of us who have had access to well-illustrated books, and to the zoological gardens of great cities.

Twenty years hence it will hardly be credited that in the year 1869 a competent naturalist, after visiting fifty of the principal museums of Europe, reported on them in the following terms:—"So far as his observations extended, he found no museum where any other purpose than a desire to produce a pleasing and convenient disposition of the specimens was manifested in the general plan of arrangement. In the few cases where there was an evident intention of showing some of the more important general features connected with the distribution of life over the face of the globe, or in the successive geological formations, the imperfection of the means has been too great to afford any great result. Among the fifty museums visited, not one was found in a building especially designed for the purpose of exhibiting collections arranged to show the history of life."* We may fairly hope that the condition of things above described will not endure much longer. The ever-widening interest in the higher problems of zoology awakened by the writings of Darwin and his followers, will no doubt, in time, move even the conservative professors and curators of the great European museums to urge upon their Governments the necessity of providing them with the means of making the collections under their charge visible embodiments of what is now known of the history, distribution, and affinities of animal life, instead of simple gatherings of curiosities, or at best mere storehouses of materials for the professed naturalist. The rearrangement of the great national collections in properly constructed buildings would, even under the most favourable circumstances, be a work of years, and one entailing great and irksome labour upon the distinguished officers of these museums. Meanwhile, there is every prospect that the hopes we have expressed in reference to the European collections will be almost immediately realised in the case of the great museum of Harvard College, under the charge of one of the most eminent of living zoologists, Professor Louis Agassiz. Thanks to the liberality of the State Legislature of Massachusetts, a sum of 75,000 dollars, payable in three annual instalments, is available for this great work, conditionally upon the raising by subscription of like sums. We are glad to learn from the trustees that the first 25,000 dollars have been subscribed, and the corresponding 25,000 dollars received from the State. The spirit which is animating Prof. Agassiz in this matter will be best gathered from his own words in the official report now before us. After paying due tribute to those who, by bringing together the great collections of the old world, laid the foundations of our present knowledge, he says: "We have no longer the right to build museums after this fashion. . . . If I mistake not, the great object of our museums should be to exhibit the whole animal kingdom as a manifestation of the Supreme Intellect. Scientific investigation in our day should be inspired by a purpose as animating to the general sympathy as was the religious zeal which built the cathedral of Cologne or the basilica of St. Peter's. The time is past when men expressed their deepest convictions by these wonderful and beautiful religious edifices; but it is my hope to see, with the progress of intellectual culture, a structure arise among us which may be a temple of the revelations written on the material universe" (p. 6). Prof. Agassiz is able to write in the following encouraging terms of the immediate prospects of his great undertaking:—"With the prospect for

* These words are to be found at p. 41 of a paper entitled, "Annual Report of the Trustees of the Museum of Comparative Zoology at Harvard College, Cambridge, together with the Report of the Director, 1868." Boston: 1869.

the next three years of an income large enough to secure the aid of competent assistants in the different departments, we shall be able to put our immense collections in complete order, and to enlarge the building sufficiently to exhibit all our specimens in their true relations. I hope that in three years any intelligent observer will be able to say that a mere walk through our museum teaches him something of the geographical distribution of animals, of their history in past ages, of the laws controlling their growths as they now exist, and of their mutual affinities—in short, that the whole will be so combined as to illustrate all that science has thus far deciphered of the plan of creation. This is my hope, and it is shared by the efficient corps of assistants on whose co-operation I largely depend for its fulfilment (p. 4)." Prof. Agassiz has set himself a noble task, and we doubt not that when it is completed, the museum of Harvard College will be an intellectual monument worthy alike of its curator and of the science of which he is so distinguished an ornament.

OUTLINES OF HUMAN PHYSIOLOGY

Grundriss der Physiologie des Menschen. Von Prof. Dr. L. Hermann. Dritte gänzlich umgearbeitete Auflage. 1870. (Berlin: Hirschwald. London: Williams and Norgate.)

WHEN this work first appeared, now more than seven years ago, it at once became our favourite handbook of physiology, and it has ever since been our constant companion. Perhaps the chief reason why it so especially commended itself to us was the fact that it served as the clearest and best exponent of what may be called the radical school of physiology. Its general arrangement differed altogether from that of most modern text-books. It entirely threw on one side that division into "functions" (function of respiration, function of digestion, and the like) which, after all, does not lessen much the labour of the author, and certainly leads the student astray, throwing, as it does, into the background, or even completely hiding, the essential oneness and solidarity of the animal body, and bringing the learner to regard the organism as a bundle of "functions," one of which might easily be pulled away without much harm being done. The leading idea of the book was to follow out as closely as possible the doctrine of the conservation of energy. That idea was kept steadily in view throughout the volume, and faithfully adhered to.

Another remarkable feature was the bold attitude taken up towards recent discoveries. These are always great stumbling-blocks to teachers and text-books. Some authors, especially German authors, put in everything that comes up, leaving time and future editions to take out again the things that wither up. Others, again, put in nothing that does not seem to be already fairly established, and the student who trusts to these alone has perhaps to wait several years, till a new edition tells him of results which have had, it may be, a most powerful influence on the progress of the science for as many years back. A third class, and of these Prof. Hermann is one, make up their mind as to what they think will stand and what will not, and so accept the one and reject the other, though both may have been published yesterday. This course being bold is of necessity dangerous; and a new edition is, in the case of such books, a most critical occasion.

An unusual popularity has now brought the present work to a third edition, and the author may certainly congratulate himself on the little which he has had to undo Many new things which in 1863 he boldly accepted have since been ratified by general consent.

The present edition differs from the preceding two in being made much larger and more complete. We trust that it has now reached its full growth, for one of the great merits of the first edition was its small size. Otherwise, beyond the increased filling up of all parts, the book does not differ materially from what it was. We are glad to see that several oversights, such, for instance, as the extraordinary statement of the first edition that the apex of the heart beats between the seventh and eighth ribs, have been corrected, and that the author gives a fair account of matters in reference to which he has been engaged in personal controversies, as, for example, in the physiology of muscle.

The boldness in selection of material to which we have referred, renders the book in some measure unsuitable for a student not sufficiently advanced to have acquired a physiological judgment; but we would urge it upon the notice of all who wish to have a clear and succinct exposition of the physiology of the present day.

M. F.

OUR BOOK SHELF

On the Strength of Beams, Columns, and Arches. By B. Baker, Assoc. Inst. C.E. (London: E. and F. N. Spon, 1870.)

THE subject matter of this little volume is of great importance to Civil Engineers. All structures resolve themselves ultimately into beams, columns, and arches, of some kind. It is therefore of great importance that the engineer should be familiar with the mode of ascertaining their strength or their resistance. We approve, in the main, of Mr. Baker's endeavour to dispense with high mathematics by substituting geometrical solutions for ordinary problems, because, unfortunately, mathematics is not the strong side of English engineers, although England has produced the greatest of mathematicians. But the author seems to labour under serious misapprehensions. He proposes his geometrical solutions, because he thinks that the use of mathematics "involves an unjustifiable waste of time, with the great contingent disadvantage that it checks the growth of sound judgment in the engineer, by giving a fictitious appearance of accuracy to his results which are not susceptible of exact deduction." This is a grievous error. The spirit of mathematics is the expression of most acute and refined reasoning; and how can the practice of intellectual reasoning check the growth of sound judgment in the engineer? The fictitious appearance of accuracy above mentioned, is altogether beside the question, because it is optional; but not so the correctness of our reasoning and arguments. The author makes the above statement in his preface, and we find, unfortunately, that throughout the volume the spirit of mathematics is sadly offended. Let us take for example the author's mode of calculating the strength of beams. He shows us how the strength of a beam may be found geometrically, and derives the formulæ for rectangular and other beams, assuming the neutral axis of the beam to pass through the centre of gravity of the sectional area of the beam.

He then proceeds to compare the calculated resistance of certain simple beams with the observed resistance as ascertained by experiment, and he finds that there is a large discrepancy between the calculated and the experimental ultimate resistances. Adopting Mr. Barlow's notation, he calls f the ultimate resistance to direct tension, F the "apparent" resistance to the same force excited by transverse strain, and ϕ the "resistance due to flexure," then $F = f + \phi$. This will be better understood by reference to figures. Mr. Hodgkinson found in the experiment under consideration, that a square inch of cast iron was ruptured under direct tension by 18,750lb., which in the above equation would be the value of f. When, however, a rectangular bar of the *same* material, one inch square, was tested, a weight of 527lb. applied at the centre of a span of sixty inches, just broke the bar. Applying now the formulæ for rectangular beams to this result, the author finds that the ultimate tensile strength of the sample under consideration must be assumed at 45,630lb. in order that the bar may be able to offer the resistance shown in the experiment; the figure 45,630 he calls the "apparent" tensile strength, and would be the value of F in the above equation; accordingly, $45,630 = 18,750 + \phi$, or $\phi = 26,880$lb., this value of ϕ being termed "resistance due to flexure," a term, we are informed, invented by Mr. W. H. Barlow; * and this new resistance being described as "lateral adhesion of the fibres;" and the author informs us, that the neglect of it may result in an error up to 190 per cent.

We have here a fine confusion of everything referring to the subject. An error is made, which to explain away, a new one must be committed; forces hitherto not suspected by mathematicians are discovered by those whose sound judgment was not checked in its growth by the infinitesimal calculus.

Does the author not know the condition which determines the position of the neutral axis of a beam? The neutral axis passes through the centre of gravity of the sectional area of a beam, provided *the resistance of the material to tension and to compression be alike.* In almost every material these resistances differ from one another, but when only a small fraction of the ultimate resistance of the material need be taken into account—say one fourth—then for practical purposes they may be assumed to be alike.

The author proceeds, however, to breaking strain, using cast iron; its ultimate resistance to tension is about eight tons per square inch, to compression about forty tons. Under these circumstances his original formula no longer holds good; the neutral axis no longer passes through the centre of gravity of the section of the beam, it approaches more and more the side where the greater resistance is offered; and were the resistance to compression infinitely great, the neutral axis would coincide with the position of the extreme fibre of the beam on the compression side, and the whole sectional area would be resisting tension only, and the extreme fibre balanced by compression. The beam would then have just double the resistance without assuming the least increase of tensional resistance of the material. The author's ϕ expresses, therefore, the amount of error into which he and others have fallen, and in case it should be zero, they will find $F = f$ as it should be, and the elaborate fabric of confusion disappears.

In other respects, the work contains much valuable information, and if the unfortunate mistake above referred to, did not crop up throughout the 300 pages, and a natural flow of clear language were substituted for a rather dogmatic and vague style, we should be glad to recommend it to the profession, which ought to have all the aid that modern science can afford. * * * * *

* Mr. Barlow, F.R.S., recently read a paper before the Royal Society on this subject, reviving his theory on the resistance of beams to transverse strain.

Meteorology. By Sir John F. W. Herschel, Bart. From the Encyclopædia Britannica. Second Edition. (Edinburgh; A. & C. Black.)

Introductory Text-book of Physical Geography. By D. Page. Fourth Edition. (Edinburgh: W. Blackwood & Sons.)

WE class these two books together as new editions of standard treatises in their respective departments of science that are among the best that can be used by students or teachers. The term "Meteorology," which has entirely lost its etymological meaning, is defined by Sir John Herschel as "the description and explanation of those phenomena which group themselves under the head of the weather, of the seasons, and of the climate," a branch of natural science of the laws regulating which we are at present almost entirely ignorant, as Dr. Balfour Stewart has shown in these pages. Writers on physical geography content themselves at present with a description of the physical contour of the globe, with some slight reference to its climatology, and the distribution of its animal and vegetable life, Mrs. Somerville's handbook being, as far as we know, the most complete in this respect. The better and more logical mode would seem to us to be, first of all to treat of the earth as a member of the solar system, and thence to deduce the laws which govern its natural phenomena; we believe that in this way such phenomena as those of ocean currents and trade winds, and the variations of climate, would be rendered far more quickly intelligible to the learner than is now the case. From his stand-point, Dr. Page's "Introductory Text-book" discusses the subject in his usual clear, concise, and systematic manner.

Rustic Adornments for Homes of Taste. By Shirley Hibberd. New Edition. (London: Groombridge & Sons.)

THAT two editions of this book have been disposed of in a short time is ample justification for the publication of a third, especially when got up in so handsome a style as the one before us. Works of this kind appeal to a large public, not over-critical as to scientific accuracy, but glad to possess that amount of knowledge which enables them to talk about ferneries and aquaria without committing any egregious blunder. We are far from depreciating the value of this smattering of science where it is all that opportunity permits to be attained. Those who like their homes to be surrounded by beautiful natural objects will here find a large fund of information respecting the aquarium, the fernery, the aviary, the apiary, the conservatory, &c., given in a pleasant style, illustrated with woodcuts and coloured plates. The volume makes altogether a very pretty gift-book, especially for a young lady.

E. Millon, sa Vie, ses Travaux de Chimie, et ses Etudes économiques et agricoles sur l'Algérie. Pp. 327. (London: Williams and Norgate, 1870.)

M. REISET, in the preface, tells us that after the death of Millon, his friends and pupils undertook the publication of a collection of abstracts of the numerous works of this illustrious chemist. The book commences with an interesting biographical notice of Millon, by Dr. Hœfer, in which the political questions which led to his long residence in Algeria are as slightly noticed as possible. The principal portion of the volume was arranged by M. Jules Lefort, with the assistance of MM. Coulier, Commaille, and the late Professor Nicklès. The book contains two hitherto unpublished papers, each extending over forty-three pages, one "on Fermentation" and the other "on the Economic and Agricultural problem of Algeria." The researches on corn also occupy considerable space. The other investigations of Millon are arranged in a very interesting manner, frequently in connected treatises. Opposite the title-page is a good photograph of a bust by M. Clément, and at the end of the book is a chronological list of the scientific works of the author, amounting in number to no less than seventy-nine.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

The Corona

HAVING been informed that my remarks at the meeting of the Royal Astronomical Society, on Friday last, have been interpreted otherwise than I meant, doubtless in consequence of my having spoken without preparation, I beg to repeat what I intended should have been the purport of my statement.

It seems to me beyond reasonable doubt that we have upon all the photographs, whether of long or of short exposure, a representative of *something which is at the sun*, since the contour of the radiance depicted upon all the photographs exhibits minima, in directions closely approximate to the extremities of the sun's axis of rotation. Furthermore, exterior to all this, and apparently masking it in a very great degree to the ordinary observer, is a much wider and more conspicuous radiance of very irregular outline, to which the name *Corona* has been ordinarily applied. The streamers and irregular projections of this latter corona appeared to me to vary in position during the period of totality in August last. They seem, moreover, to have no connection with the positions of the prominences, nor yet with that of the solar axis, and hence I infer that this phenomenon arises from something *which is not at the sun*.

London, June 15 B. A. GOULD

Euclid as a Text Book

I HAVE been waiting in the hope that Mr. Levett's letter (NATURE, No. 30, pp. 65, 66) would elicit a response from other members of the "rank and file" of mathematical teachers. No one having come forward, I venture to do so, lest the subject should again drop. Mr. Levett's suggestions appear to me at least worthy of some little ventilation, and I hope some leader will be induced to utter a note on the subject. Knowing that many of the leading geometers of this country are favourably disposed to the "reform" movement, I feel sure their silence is not attributable to indifference. In the meantime it is my opinion that no isolated efforts will bring about such a reform as will thrust out Euclid from our schools; united action is what is wanted, and then "a long pull, a strong pull, and a pull all together." I could easily select from the four Universities of Oxford, Cambridge, Dublin, and London, four geometers who could, I believe, if it be possible, bring out in concert a work which should be a fitting rival of the old-world geometry, command the attention which such a work ought to secure to effect the change desiderated, and convince gainsayers. A scheme might be drawn up in concert, the working out of the details committed to one, and the work appear under the united names of the body. Then as to the number of the "rank and file" willing to give their support to such a plan, possibly some mathematical master at one of our public schools (I could in this case also make a selection) could give much valuable information. I hazard the above remarks, not wishing the ball set rolling in the columns of NATURE to come to rest, until the change has been effected or its inexpediency irrefragably demonstrated, *valeant quantum valent*. R. TUCKER

University College School, June 11

The Interior of the Earth

UNDER the signature of Z., I find in your issue of the 16th inst., a short notice of "The Interior of the Earth." A clerical error made during the Epsom or Ascot races, such as F. L. instead of E. I., is excusable, though not comprehensible; a misquotation which he has made may be pardoned, but a misrepresentation purely from neglect of reading is quite unbearable. He tells your readers that I proceed "to explain the earth's heat and volcanic phenomena by a like action on buried vegetable matter." If he had read p. 33, he would have found that to the cause alluded to "I partly assign the changes which have taken place in the strata connected with our coal pits." Z. thinks that a perusal of Lyell's "Principles" would have stopped the writing of my book, I beg to tell him, that this work was the first that convinced me of the great geological error which I have exposed. Z. does not seem to have read my reasons for using Page as my text-book; I hope he is not hurt at being left out himself, but if I had quoted from all the books I have read on the subject, I should have been as unintelligible as some of them.

A sneer is not a review, but if Z., or any one else, can prove to me that an internal and inherent heat within the earth has caused, or does cause, the phenomena alluded to, I will with pleasure renounce my present creed; but, till then, I merely say that as I have controverted the theories of others, I shall be glad to read any controversions of my book, if written in the same spirit of inquiry. H. P. MALET

Prismatic Structure in Ice

THE enclosed letter, which has just reached me from Canada, seems to me so interesting that I venture to hope a place may be found for it in the columns of NATURE. I may, however, state that I still adhere to my conviction that the vertical chains of air bubbles are the consequence of the prismatic structure; since in all the cases I have seen they are too regular to have been formed as my correspondent suggests. Although I believe it is an established fact that, speaking generally, ice contracts with cold, I am not aware that its demeanour at a temperature of about 32° F. is quite so accurately ascertained; it seemed to me, when investigating what had been written on the subject, that further information was needed on this point. The prismatic structure appeared, and still appears, to me inexplicable on any other theory than that of contraction.

St. John's College, Cambridge T. G. BONNEY

"In one of the March numbers of NATURE I see a letter over your signature on the prismatic structure of ice, and as our climate gives us favourable opportunities of observing this and other curious facts respecting ice, I am induced to address a few words to you on the subject.

"The ice on our inland lakes is generally two or three feet thick. As the spring advances, an inch or two may be melted away from the lower surface, and somewhat more from the upper one, but the thickness is not materially reduced until its final disappearance. The first sign of the approaching break up is that the ice becomes dry, from the prismatic structure having commenced to show itself, allowing the surface-water to percolate through the interstices; it is then said to be honey-combed. In this state the lower layers of transparent ice are still solid, though if you cut out a block the prismatic structure is very evident; but the upper portion, which has been formed from a mixture of snow and water, readily breaks up under your feet into little granules of ice. The next stage is that the ice becomes black, showing that it is soaked as it were with water; and if at this time there is any open water, as where a river falls into the lake, and wind enough to create a swell, the whole surface of the ice may be observed to undulate. Even then, sometimes, a single night's frost may make all firm again, and you may even trust horses upon it. If the ice now breaks up prematurely with a high wind, it becomes a mass of spiculæ of ice which have not reached the melting point, and which I have seen accumulate to the depth of six or seven feet against the edge of the ice, which has not yet broken up. But if there is no wind, the whole surface of the lake may appear an unbroken sheet of black ice, still a couple of feet thick, till, in an astonishingly short space of time, sometimes not more than a few minutes, it disappears as if by magic. So sudden is this disappearance, that the ice is popularly believed to sink.

"I once had a very good opportunity of noticing this sudden disappearance. I had built on the ice during the winter a pier of logs filled with stones, and when the spring came, it settled down to the bottom, carrying with it a large cake of the ice. When the lake had opened, I went round the pier in my canoe to see if it had settled evenly. There at the bottom, in six or seven feet of water, lay the cake of ice it had carried down, with the chips still imbedded in it which we had made in building the pier; and, as I looked, blocks would break off of a foot or more in thickness, rise to the surface, break up into spiculæ, and almost instantaneously disappear.

"I quite agree with you that these prisms have no connection with the hexagonal form of ice crystals, but I doubt your explanation that they arise from the contraction of the ice as it approaches the melting-point. Does ice contract under such circumstances? Although water expands in freezing, and, *vice versa*, occupies less bulk when reconverted into water, yet, as long as it remains ice, I conceive that it contracts with cold and expands with heat like other substances. It is certain that, after a night's hard frost, a surface of glare ice will be covered with a multitude of small cracks from the contraction; and larger cracks will sometimes extend through the whole thickness, with a report almost like that of a cannon. I knew a case of a railway bridge, built on piles over a shallow lake, which was entirely destroyed by the alternate expansion and contraction of the ice with variations of temperature. With a spell of cold the ice would be split up with innumerable cracks, into which the water insinuated itself and froze. With warmer weather the whole expanded, shoving the ice up on the shores. On a fresh contraction, the ice could not be withdrawn from the shores, but cracked again in preference. The consequence was, that there was a constant shoving from the middle of the lake towards both shores. The piles in the middle remained upright, but the nearer they were to each shore the more they were driven out of the perpendicular. The damage was great the first winter, but it was repaired. The next winter, by cutting up the ice with ice ploughs, and by making embankments from each shore, the damage was sought to be arrested; but every winter it got worse, till the bridge had to be altogether abandoned; and whilst the piles in the middle are still upright, those near each shore are now laid almost flat. It is to this constant motion in one direction, arising from alternate expansions and contractions, that I have always in a great measure attributed the downward progress of glaciers.

"The true explanation of the prismatic structure appears to me to be the lines of air bubbles, which you yourself notice. These are visible in all ice before any thaw has commenced, and in the process of freezing they seem to be formed in vertical lines. When the thaw occurs, these lines of bubbles form the centres, as it were, from which it penetrates in every direction through the mass. "JOHN LANGTERS

"Ottawa, May 25"

Etna in Winter

THE ascent of a high mountain always gives plenty of opportunities of observation and experiment, but that of the prince of the volcanoes of Europe, and at the same time one of the grandest of its mountains, must always be an undertaking of paramount interest to the student of the phenomena of Nature.

We leave the edge of a plain with a semi-tropical luxuriance of vegetation (the great plain of Catania, where Ceres taught mankind husbandry, and where common belief states wheat to be indigenous), and pass through a country so rich in its profusion of orange, lemon, fig, and olive trees, so-called American aloes, prickly pears, vineyards, peach trees in full bloom,* &c., that it would remind us forcibly of Algiers, did not the irregular surface of the numerous lava currents (on which the prickly pear is cultivated extensively) and the lava-built walls and buildings around bring back Auvergne to our thoughts.

Still higher above the sea level we find karouba trees, with umbrella pines and dwarf oaks in abundance; fields of flax and of wheat (a foot high) and other signs of a more temperate climate; nearer to Nicolosi (the village from which the ascent is made) in traversing the rugged lava current of 1536 we are struck by the peculiar appearance of the bushes of Etna broom which flourish on its surface. Even on the cones above Nicolosi up to a height of about 1,300 metres above the sea level, the vine is still cultivated and excellent wine produced.

After supper and a short nap we start at 10 P.M. with a guide, mules, and a muleteer, and well provided with provisions and wraps (taking with us a few thermometers, &c.); and passing by the Monti Rossi, which were formed during the remarkable and well-described eruption of 1669, we traverse various lava currents and fields of cinders, and find ourselves at last in a straggling wood of stunted oak trees succeeded by one of Italian chestnuts, in which latter we come upon the Casa del Bosco (a solitary house, uninhabited in the winter) after a rather rough ride of nearly three hours. Here we rest for half an hour, warm ourselves at a wood fire which is soon made, and take our supper; then at 1.15 we start for our laborious ascent; we come upon the snow in about an hour, and (having chosen a starlight night after a continuance of fine weather) find it dry and firm; now the work begins; leaving the mules and their driver, we toil on slowly and steadily, not speaking for fear of wasting strength or getting out of breath, and after a long, stiff climb up a very steep surface of almost smooth snow, which scarcely gives a hold to one's feet, we arrive at the Piana del Lago soon after 4 A.M. Here we have a comparative respite, and march merrily up the slight ascent, with the black summit of the cone in front of us, and looking so close that we can hardly believe the guide who says that it will take us nearly two hours to get up to it. At about five o'clock we arrive at the Casa degli Inglesi, where travellers sleep in the summer, but which is now all but buried in snow. On we go (as we have no time to spare before sunrise), the guide pointing out where we might see the Torre del Filosofo were it not entirely covered, and in a quarter of an hour, after crossing several fields of thin, broken ice, and nearly falling into sundry uncomfortable-looking holes, which one doesn't see until one has put one's foot through the crust of ice and snow which conceals them, we reach the foot of the actual cone, and look up its steep sides with some dismay, knowing, as we do by manifold experience, that the ascent of a cone of loose cinders 300 metres high, and at an angle of 40°, is no joke; our work is made somewhat easier by the snow with which the base is covered; but we soon get off this and hurry on to get to the top before the sun rises. Before we are half way up the cone we find the necessity of stopping to take breath so urgent, that we halt and look behind us at the inexpressibly magnificent colours in the sky; this we have to do several times, and were it not for Pietro's "Avanti!" we should go to sleep as we walk; besides which our legs have given way at the hip joints and seem no longer to belong to us; perhaps also some of us may feel a sense of nausea, and those least used to such excursions doubtless have a sharp pain in the knee joints. By screwing up our courage, however, we get gradually higher, and soon the fumes of sulphurous acid that arise around us tell us that we can't have much more to do. Five minutes more and we look down into the immense crater, and instantly turn round and see the sun rise above the horizon and light up the beautiful island at our feet.

Our ascent has been a capital success; we have had a fine starlight night, firm snow, and a good guide; there is not too much vapour, &c., and the brisk north wind drives it away from us. We soon find out that although the soles of our boots are being burnt by the hot cinders, our right hands (which held the alpenstocks) are frozen, and during ten minutes we experience excruciating pain in them. After a hearty breakfast we look around us, and see that the heated state of the ground is due to the continual slow oxidation of the sulphur contained in the ashes or lying about on the surface, and not to any internal action of the volcano. Far down in the crater, where there is less sulphur, the surface is covered with snow, and at the very bottom of it is a huge plug of snow also. With some difficulty we make our way through the suffocating vapour to the highest point of the edge of the crater, and thence look down upon the marvellous scene.

The effect is almost unique, from no other point, except perhaps the Peak of Teneriffe, has one so unbounded a view. We find ourselves at a height of nearly 11,000 feet above the sea level, with no other mountain of considerable height within the horizon at all: the "garden of Europe" stretched out at our feet, beyond its borders the sea, on all sides extending far away into the dim distance, and confusing itself with the sky; to the north of us Calabria, the "toe" of Italy, bounded by mist and looking like an island; we see yonder Monte St. Giuliano (the ancient Eryx), there the hills around Palermo; to the north, the point of Milazzo, very plainly indeed; beyond it, the chain of the Lipari Islands, apparently raised up into the sky (a rather striking phenomenon); farther east, the island seems to touch Calabria, and there are the Straits of Messina; here is Catania, from which we have come: there Syracuse, and in that direction Girgenti, the site of the famous Greek temples; farther west Marsala with its vineyards. All around us, at the base of the mountain, we see the secondary cones, and look down into their craters, while the distant hills look like slight irregularities on the surface of the island, although some of them are so high as to be covered with snow. What with feasting our eyes on the grand view, looking down into the immense crater, the deepest and steepest that we have ever seen, and collecting specimens of the variously-coloured cinders, &c., around us, we have spent two hours on the summit: it is eight o'clock, and our guide warns us that the heat of the sun will fast melt the surface of the snow, and render the descent more difficult and more dangerous. We could not walk round the edge of the craters on account of the vast quantities of stifling vapour that arise from some parts of it, even if we wished to spend another hour in doing so. Taking

* March 4th.

then a last look into the huge abyss, we run easily down the side of the cone, and are in a few minutes at the Casa degli Inglesi again. Here we turn off towards the eastern side of the mountain, and soon come upon the edge of the Valle del Bove, to enjoy perhaps the most remarkable spectacle in Europe. We find ourselves now on the summit of an almost vertical cliff, nearly 4,000 feet high, which constitutes the head of an enormous cleft or valley, about eight or ten miles long by four or five broad; it is as if a piece, constituting about one-sixth part of the mountain, had been cut out of it. On either side it is bounded by cliffs of from one to three thousand feet high, and consisting of layers of lava and ashes traversed by dykes of basalt, trachyte, &c.; several volcanic cones are seen in it, of which Monte Simone, to the northern side, with its lava of 1811, and Centennario, Calanna, and Giannicola to the southern side, with the barren black lava of 1852, are the most noticeable; this immense depression was caused, according to the opinion of Sir Charles Lyell and of Gemmellaro the great Sicilian vulcanologist, by the subsidence of an ancient felspathic volcano, which must, according to calculations made from the inclination of its lava currents, have been much higher than the modern pyroxennic one. (La Vulcanologia dell' Etna, del Professore Carlo Gemmellaro; Catania, 1858.) Such a subsidence is well illustrated on the small scale by the Cisterna, a round hole about 300 yards in diameter, and at least 200 feet deep, which was formed precisely in the manner just mentioned during the eruption of 1792, and which we can see on our way back to the Montagnola; indeed, when we consider how much material is ejected during the various eruptions in the form of lava and of ashes, &c., we see that it would be strange if subsidences, and great ones too, did not happen occasionally.

We now descend quickly, finding our last night's tracks behind the Montagnola, and by 10.30 are off the snow, and find the mules ready for us. In returning to Nicolosi we are able to observe the various lava currents, and to study their sections in the channels of the streams which rush down during the melting of the snow in the summer months, and also to notice the gradual change in the vegetation which the darkness prevented our remarking during the ascent.

We find the heat more and more oppressive, and are afflicted with very severe headaches; on arriving at Catania we find it covered by a dense fog (an extremely unusual occurrence there), and so the congratulations on our safe arrival are mixed with wishes that the weather had been more favourable.

In a future communication some remarks will be made on a few observations taken during this excursion.

W. H. CORFIELD

Paraplegia in Kangaroos

SOME time ago I obtained from Mr. Fairgrieve the bodies of two Kangaroos, male and female, which died during the visit of Wombwell's Menagerie to the West of Scotland. In the female, which I received first, there was extensive ecchymosis in the nuchal region strongly suggestive of bites inflicted by her cage companions. To this I was disposed to refer the softening of the cervical spinal cord, which struck me when removing the brain. On visiting the menagerie, however, I found that her male companion was completely paraplegic, and that he had exhibited the same symptoms. The paraplegia had been progressive, and at the date of my visit, respiration was markedly thoracic. The animal was excited, but I could not satisfy myself whether this indicated cerebral disturbance or arose from the contagion of fear, a younger specimen in the same cage being much alarmed at my approach. The animal died at some distance from Glasgow. I made a careful post-mortem, and found no lesion save in the spinal cord and medulla oblongata. The removal of the cord was difficult, on account of the thickening of the membranes, and their adhesion to the bony walls of the canal. The cord was not merely softened; it was semifluid as far up as the origin of the cervical plexus, and welled out like thick cream from an accidental puncture of the sheath. Dr. Joseph Coats who assisted me in the examination, failed to detect any fatty degeneration of the nervous tissue. Its disintegration was, however, very complete. The other organs were healthy, and the body was well nourished. The disease was manifestly of short duration, and I can only hazard this conjecture as to its cause, that the cage was placed at the angle of the square formed by the cars, and that its inmates were thus exposed to draughts and damp, giving rise to acute meningitis. As, however, an Australian sportsman informs me that something of the same kind has been observed in Kangaroos kept in confinement, and thus deprived, to a large extent, of their customary exercise, I ask space for this abstract of the case, in hope that some of your contributors may be able to throw light on an interesting pathological question.

JOHN YOUNG, M.D.,
Glasgow University Keeper of the Hunterian Museum

Geology and the Chatham Dockyard

BELOW the Alluvial deposit of St. Mary's Island is a very irregular surface of gravel, varying in thickness from 2 to 12 feet, and composed of flints but little rounded, and pebbles of Tertiary Sandstone; beneath the gravel is the Chalk. Now, the success of the Chatham Dockyard Works depends upon the stability of foundations that are built on piles driven into the underlying gravel, through which percolate considerable streams of water; this water must denude the chalk to an appreciable extent and form pot-holes, and the subsidence of the works can but be a matter of time. I can form no idea of the rate at which the Chalk would be denuded under the above conditions, as I am not aware of any experiments having yet been made on the "Action of Water on Chalk."

R. C. HART

Dust and Disease

PERMIT me to add my mite to Mr. Horace Waller's theory respecting the utility of mosquito curtains in warding off fever, generated by the miasma of decaying vegetation.

For the last twenty-five years I have held to this opinion, and acted on it in all my wanderings in the jungles of Ceylon, on the east coast of Africa, and in New Zealand, and I am convinced of its great utility. I have always likened it to Davy's "safety lamp," and I believe that over and above the "sieve-like" property, which a few days' use imparts to it, its value is great as warming the air which passes through its meshes, and keeping the temperature within it more steady and equal.

When the body is relaxed in sleep and the pores of the skin act freely, then is the time that the deadly miasma, cold and damp, even in the tropics, seizes on its victim. What jungle traveller does not know the feeling of the air an hour and a half or two hours before daylight? But the warmth from the body and breath within a well-secured mosquito net, I think effectually protects the sleeper.

This morning I compared the temperature outside and inside my mosquito net, and found it differ 8°, being 62° outside and 70° within, and even this was not a fair trial, for the bed is a large double one (two persons in it), exposing a large surface to the external air; the mosquito curtain being the largest sized *Net* that can be got (and not *Leno*) which I would advise for a travelling curtain in fever latitudes; and moreover, as our mosquito season is past, not tucked in all round as a well-secured curtain should be, yet with all these disadvantages the temperature inside was 8° warmer.

Then, again, who doubts that the body, invigorated by sound sleep, is not more able to resist disease in the day-time? Without a net in mosquito lands I find sleep impossible, and I suppose others do the same.

Let me therefore raise my voice in favour of the mosquito curtain, and advise all travellers in fever countries to look on it as their sheet anchor.

E. L. LAYARD

Cape Town, Cape of Good Hope,
May 3

HEINRICH GUSTAV MAGNUS

IN giving expression to the sympathy generally excited by the loss of Magnus, Professor Tyndall has raised the interest of the British public in a philosopher's life, simple, yet most eminently useful. At the present moment a mere outline of it is all we can venture to offer. Unable to appease, it may yet prove sufficient to keep up the interest in Magnus's life until a fuller biography will do more ample justice to his merits.

Heinrich Gustav Magnus was born on the 2nd of May, in the year 1802. Four years later, Berlin, his native town, had to resign its position as the residence of an independent kingdom. The French war raged with ever-increasing fury, and though Mr. Magnus, the banker, found the means of sheltering his children from the most severe consequences of the national calamity, their youth was naturally a severe one. It appears more than probable that the energy and ambition which raised all of them high above the level of mediocrity, may have originated in the stern impressions of their childhood. Thus one of the brothers, Edward, rose to the highest distinction as a historical painter, and is now one of the ornaments of the Berlin Academy of Arts. A younger brother distinguished himself as a physician; while the eldest, whose death preceded that of Gustav by some months only, continued and extended his father's banking business. A son of the latter became prominent during the last war in Mexico, where, representing Prussia at the Court of Maximilian, he showed great energy in his endeavours to save that misguided monarch's life.

The peculiar talents of Heinrich Gustav showed themselves at an early age. He exhibited a rare proficiency in mathematics when a mere child, and soon expressed a wish to devote himself to the study of nature. At the Berlin University, founded some years before, the Chair of Chemistry had passed from the hands of Klaproth into those of Mitscherlich, who was then at the height of his reputation. Young Magnus was twenty-three years old when he published his first paper on the pyrophoric nature of finely-divided metals. Two years later he received his Doctor's degree, and published a dissertation on tellurium. He subsequently passed twelve months at Stockholm, in the laboratory of Berzelius, who gave to Germany some of its greatest *savants*, of whom Wöhler, in Göttingen, and Gustav Rose, in Berlin, now alone survive. From Sweden he removed to Paris, returning to Berlin in 1831, and began there his university career as a lecturer on technology, a subject which he continued to teach till last summer.

HEINRICH GUSTAV MAGNUS

Nearly all his researches published during this time and up to 1833 were devoted to pure chemistry. A latent interest for natural philosophy can, however, be traced already in his earlier publications. Thus he determined the temperature at which oxide of iron is reduced by hydrogen, and analyses of several minerals were followed by determinations of the decrease of density which vesuvian and granite undergo in fusion. These determinations excited much interest at a time when the doctrine of isomerism was making its first appearance, and every two substances having the same composition and yet exhibiting different properties, were subjects of astonishment and of doubt. He even published papers on capillarity, and on the temperature of the interior of the earth and a thermometer fitted to register the same, as early as 1832. But the researches on which his early fame was founded are of a strictly chemical nature. A paper on the combinations of protochloride of platinum in 1828, contained the description of what is now called Magnus's salt, one of the first known of that important series of metallic ammonium salts, which acquired later an increased importance, as a support of the theory of substitution, and a link between mineral and organic chemistry. Five years later, in 1833, appeared his paper on the decomposition of ethyl-sulphuric acid, and on two new acids, ethionic and isothionic acids. These acids (together with the sulphobenzolic acid discovered by Mitscherlich in 1834) became the starting point of numerous discoveries. They increased our knowledge of isomerism; they prepared the way for the modern views on the constitution of natural bodies, and they enabled Strecker, in 1854, to form, artificially, a constituent substance of bile, taurin.

In the same year (1833) another important discovery concluded, so to speak, Magnus's career as a chemist. Together with Ammermüller, a doctor of medicine and head master of a public school in Würtemberg, he published his researches on periodic acid.

When Magnus appeared again before the scientific world, it was in a new science. He was created Professor of Natural Philosophy in 1834, and no research of his was published during the following three years, evidently spent in qualifying himself for his new position. Researches on steel magnets and on the boiling of liquids reopened the series of his discoveries in 1836; still he had not escaped the sway that chemistry exercised over his mind. Papers on the composition of a fossil resin, ozokerite, on the gases contained in blood, and on the combination of ethylene with sulphuric anhydride (carbyl-sulphate) were published in 1837 and 1838, and even later researches on the formation of tar from ethylene, and on the allotropic modifications of sulphur (1856),* show how much chemistry lost when natural philosophy took possession of Magnus's talents and energies. Later his modesty urged him to disclaim the honours so largely gained through his chemical researches. When after the opening of a university laboratory by Prof. A. W. Hofmann, the expanding scientific interest led to the formation of the German Chemical Society (in 1867), Magnus could only be prevailed upon with difficulty to become one of its vice-presidents, and although he worked on the committee with zeal, offering assistance and advice wherever it was needed, and publishing a paper on the diathermanity of chloride of potassium in the Reports of the Society, he pretended that he had lost all claims to be regarded as a chemist.

We have to revert, therefore, to the second side of his scientific work, his researches in natural philosophy. A determination of the expansion of air, instituted at the same time (1842) and in an analogous manner, by Magnus in Berlin, and by Regnault in Paris, and yielding all but absolutely the same numerical results, proved the exactness of both physicists. The most admirable conformity distinguished likewise researches on the tension of vapours, which both *savants* executed independently of each other in 1844, by entirely different methods. Relating chiefly to the tension of steam, the results thus obtained are as important for practical as for scientific purposes. Researches on the tension of vapours given off by mixtures of different liquids, and a comparison of the mercury thermometer and the air thermometer, preparatory to the great investigations just referred to, were published at the same time.

In 1855 Magnus investigated the form which jets of water assume when issuing from apertures of different shapes, and thereby opened to experimental study the surface-tension of liquids. His inquiry extended to the manner in which the motion of the aperture influences the form of the jet. Two years later he published detailed investigations on electrolysis. The discussion of this complicated question he founded on the theory of chemical substitutions. The temperature of vapours and the conducting power of gases formed the subject of his researches up to 1861. Until then gases had been considered as non-conductors. He proved that hydrogen conducts heat in the same way as do solid bodies, and thereby established a new and striking analogy between this element and metals.

During the last years of his life the radiation of heat formed the chief object of his researches. A paper on the polarisation of the dark rays of heat, the discovery of the diathermanous nature of native chloride of potassium, and lastly a full research on the emission, absorption, and reflexion of heat radiated at low temperatures, were the results of this protracted and fertile investigation. He showed that heat from different sources is refracted under different angles, and absorbed in different proportions by the chlorides of sodium and of potassium, by fluor-spar and other substances. He thus proved, that, if our eyes were able to distinguish different rays of heat, we should see the different substances glowing in the most varied colours at ordinary temperatures, just as we see them emit different rays of light when exposed to heat and observed with the spectroscope.

The receptacle of all his researches is the "Annals of Chemistry and Natural Philosophy" (*Annalen der Chemie und Physik*), published by his friend Poggendorff. He formed a fine collection of scientific apparatus, afterwards bought by the University and put under his control. As a lecturer, Magnus was a pattern of clearness. He loved teaching, and his diction, though plain, showed the high culture of his mind. While in his lectures he aimed at being comprehensible to the large number of students who wished to learn the rudiments of science, he instituted special classes for those who longed to enter into a deeper study of natural philosophy. Graduates and undergraduates assembled around him once a week, to enjoy what he called physical conversations. Here students in turn reported on investigations recently published, the master criticising the report and opening a discussion on those points which appeared to deserve a fuller explanation. Some favoured pupils were instructed in the methods of physical researches in his private laboratory, the master allotting subjects to them, urging them above all to exactness, and warning them against drawing hasty conclusions from their experiments. Many professors of natural philosophy, who have since obtained fame or reputation, have been educated in these classes. From a long list of names we will but mention those of Tyndall, Clausius, Wiedemann, Heusser, Quincke, Palzow, Villari, and Kundt. The laboratory joined his apartment, and he was thus enabled to watch from his sick-bed the investigations that occupied his thoughts. Magnus's health had been impaired for many months. He was suffering when he visited the last meeting of the British Association at Exeter. He was ill when he presided at the banquet given to Professor Hofmann on the 8th of January. Still he continued his work up to the beginning of February, when weakness and excruciating pain forced him to give up his lectures. He foresaw his death, and made the most minute arrangements, order being one of the characteristic properties of his mind. "I have written to you to ask for your advice," he addressed his physician, "but I foresee that my case will give you but little satisfaction."

Magnus married the daughter of M. Humblot, a well-known publisher. His wife, as well as two daughters and one son, survive him. The circle that assembled at his house was very large, and included the leading members of every profession, members of the university, merchants, statesmen, and artists. But he was equally accessible to every unknown youth who wanted his advice and assistance. Ever ready to help, he bestowed his aid, as if he received, not as if he conferred, a favour. Gentle-mannered, conciliatory, and persuasive, he was the mediating element of every society. Nothing can show better the kindness of his disposition than the love which, not his family or his pupils only, but even his domestics, bore for him. A faithful laboratory servant, who took care of his instruments and also nursed him through his last illness, bears witness that he could not endure to see unhappiness or unpleasantness around him. "Why," he would ask sometimes, "will you make life difficult to yourselves? Is it not sufficient your Master should make it difficult for you?"

His death is therefore felt, not only as a severe loss to science, but as a personal pain, by all who had the good fortune of approaching him. Numerous were those who, on the 8th of April, thronged the room where his coffin stood, hidden under palms and flowers. Some parting words were spoken by Dr. Müllensiefen, Professor of Divinity, and a song of Mendelssohn, sad, yet cheering, ascended from his grave.

A. OPPENHEIM

* The latter investigation contained an error which was afterwards corrected by its author, and originated a new discovery. Magnus found that sulphur acquired a deep red or black colour when fused with minute quantities of various organic substances. This change was at first ascribed by him to an allotropic modification of the element.

RECENT ADDITIONS TO THE ZOOLOGICAL SOCIETY'S GARDENS

In April last the total number of additions to the living collection of the Zoological Society of London was 124. Of these, twenty-one were born in the Gardens, forty-four were acquired by presentation and fifty-two by purchase, while one was received in exchange, and six merely "on deposit." The "departures" during the same period, by death and otherwise, were ninety-one. Among the more noticeable additions were :—

1. A female of one of the smaller forms of Rusine deer, purchased by a dealer on the 13th of April, and stated to have been received from the Philippines. This animal is quite distinct in its small size and dark brown fur from any other member of the group now or lately in the Society's collection. If the assigned locality is correct it may probably belong to the Rusa deer of the Philippines, which was first named *Cervus mariannus* by Desmarest, as having been found living by the French naturalists during the voyage of the *Uranie* at the Marianne Islands. Here, however, it was stated to have been introduced from the Philippines. It would be very desirable to increase our knowledge of the deer of the Philippines. Probably there is more than one species that occurs there.

2. A Sooty Crow-Shrike (*Strepera fuliginosa*), purchased on the same day, is one of a peculiar group of Australian birds, of which the Society previously possessed examples belonging to two other species. These are all placed in the cages outside the "Parrot-house," which are devoted to the reception of the hardy species of crows (*Corvidæ*) and their allies, and at the present moment contain examples of several other species of great interest, such as the yellow-billed chough of the Alps (*Pyrrhocorax alpinus*), the chough of our own coasts (*Fregilus graculus*), the Chinese Jay-thrush (*Garrulax sinensis*), and the Australian crow (*Corvus australis*).

THE HUIA BIRD (*Heteralocha gouldi*)

3. A Vulturine Guinea-Fowl (*Numida vulturina*) presented by Dr. John Kirk, C.M.Z.S., H.B.M. Acting Consul at Zanzibar.

For many years this remarkable Guinea-Fowl, which is peculiar for having the head entirely devoid of feathers, and for the long ornamental hackles surrounding the neck, was only known to naturalists from a single specimen, formerly in the United Service Museum. This was figured in Mr. Gould's "Icones Avium," but its exact locality was unknown. More recently, since the eastern coast of Africa has been more thoroughly explored, it has been discovered that this bird is by no means uncommon on the southern part of the Somali coast, and in the adjacent parts of continental Africa. Dr. John Kirk, the well-known companion of Dr. Livingstone in the Zambesi expedition, who has been lately resident at Zanzibar, as acting Consul, has communicated several notices upon this Guinea-fowl to the Zoological Society, of which he is an active correspondent. In one of his letters he says that "it seems to be common at Lamoo, a port situated on the east coast of Africa, in about 2° S. lat. The officers of H.M.S. *Syria*, when lately there, saw several in the market, but used them for the table, not being aware of their great rarity." More recently Dr. Kirk succeeded in securing for the aviaries of the Society the present female example of the species. This fine bird was procured at Brava on the southern part of the Somali coast, just to the north of the equator, and was conveyed, along with a collection of other animals presented to the Zoological Society by Dr. Kirk, in the steamer, *Malta*, through the Suez Canal to Marseilles, under the kind care of Captain Mackenzie.

4. A jackal, stated to have been brought from the River Fernand Vas, south of the Gaboon, and to be the animal referred to in Du Chaillu's well-known "Explo-

rations and Adventures in Equatorial Africa" (p. 243), in the following passage :—

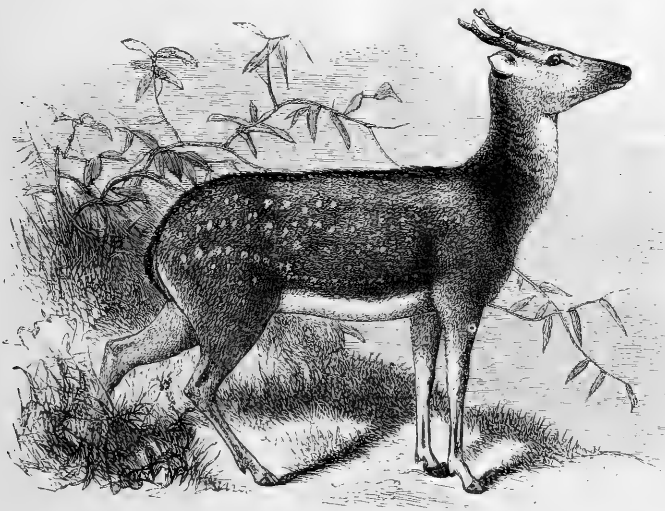
"Before we got to town again, I shot a *mboyo*, a very shy animal of the wolf kind, with long yellowish hair, and straight ears. I have often watched these beasts surrounding and chasing small game for themselves. The drove runs very well together, and as their policy is to run round and round, they soon bewilder, tire out, and capture any animal of moderate endurance."

Such is M. Du Chaillu's fragmentary notice of this animal, of which, however, he does not appear to have sent home specimens. After endeavouring in vain to find a name for this distinctly-marked species of *Canis*, which is readily recognisable by the black and white stripes along the flank, and the long black tail with a black termination, I proposed at the meeting of the Zoological Society, on May 12th, to call it *Canis lateralis*. Dr. Peters, however, has since suggested to me that it may be the *Canis adustus* of Sundeval, and this identification is probably correct, although our example does not agree very well with Sundeval's description. I may also remark that there is no example of *Canis adustus* in the British Museum, and that, without the aid of specimens, the differentiation of the various species of *Canis* is by no means an easy task.

In the month of May the number of additions to the Society's collection of living animals was still more numerous than in April, amounting altogether to 200. Of these fifty-four were received as presents and eighty-three acquired by purchase ; forty-five were bred in the gardens and eighteen were deposited for safe custody. The number of departures in May, by death or otherwise, was seventy-five.

Amongst the 200 acquisitions in May were several of great interest, viz. :—

1. A male deer, forwarded to the Gardens from Singapore by order of H.R.H. the Duke of Edinburgh. This is quite different from any other deer yet obtained living



PRINCE ALFRED'S DEER (*Cervus alfredi*)

by the Zoological Society. It is obviously allied to the axis or spotted deer of continental India, and may be the Malayan form of that species. It differs, however, in its smaller size and smaller ears, and in the dark coffee-brown colour of the fur. I have not been able to find any designation applicable to it, and, at a recent meeting of the Zoological Society, have proposed to call it *Cervus alfredi*, after the Prince, who has transmitted the present individual to us.

2. Three examples of the crested or bladder-nosed seal of the Arctic Seas (*Cystophora cristata*), purchased May 5, out of a whaling vessel, which brought them into Dundee. These are the first examples of this seal that have reached the Society's gardens alive, and are of much interest, as making us acquainted with the external form of a very distinct genus of the *Phocidæ*. The bladder-like excrescence on the forehead, which attains an extraordinary development in the adult male, is but very slightly shown in these young animals, but a look in the mouth at once shows their difference from the typical seals of the genus *Phoca*.

3. A huia-bird (*Heteralocha gouldi*), from New Zealand, purchased May 18th. This bird is remarkable for the great difference in the shape of the bill between the two sexes, as will be readily understood by reference to the accompanying illustration, in which the short-billed individual is the male and the long-billed the female. The figure of the male is taken from the Zoological Society" specimen, the head of the female is copied from Mr. Gould's plate of this species in the "Birds of Australia." Such a divergence in the structure of the beak of the two sexes is very uncommon and scarcely to be paralleled in the class of birds. It is difficult to guess at the reason of it, or to explain it on Darwinian or any other principles. The story is that the male employs his stronger instrument to hew away the wood that covers the grub, and the female her more delicate organ to extract the precious morsel. Unfortunately, we have as yet only one sex of

this bird living in the Society's Gardens, but it is so far certain that our male is evidently very fond of grubs, and will search for them with eagerness in rotten wood. He does not, however, seem obliged to wait for a female of his own species to extract them when discovered, but picks them out for himself. A somewhat parallel case of difference of the bill in the male and female occurs in the humming-birds of the genus *Grypus.**

4. A Tuatera lizard (*Sphenodon punctatum*), purchased May 20th.

This not very attractive-looking lizard is really one of the most extraordinary reptiles now known to exist on the world's surface. In several important particulars of structure it differs from every other known saurian, insomuch that Dr. Günther, who has published an elaborate memoir on its anatomy,† has proposed to constitute it of itself a distinct order of reptilia, equal in systematic rank to the ophidians and saurians. It differs from all the known members of the latter order in having the quadrate bone firmly anchylosed to the skull, and in the entire absence of an intromittent copulatory organ. The vertebra are amphicælian, as in the Geckoid lizards. Dr. Gray first described and figured this reptile under the name *Hatteria* (!) *punctata*, and it has been so generally designated until lately, when it was most fortunately discovered that the generic term *Sphenodon* had been previously applied to a specimen of its skull in the museum of the College of Surgeons. It has thus become possible not to be obliged to employ so vile and barbarous a term as *Hatteria* for the name of this important animal. Dr. Günther, when he wrote his memoir, supposed that this reptile was extinct or nearly so. But one living example has reached England since that date, and more than one, I believe, in spirits. From an article published by Dr. Bennett, of Sydney, in the *Morning Herald* of that city, it appears that so recently as December 1851, this lizard was abundant in one of the islands in the Bay of Plenty, on the north coast of New Zealand. The island in question is one of four small volcanic islands, distant about eight miles from the coast, and situated opposite to the mouth of the Wakatane river. A party of officers, who visited it upon the occasion referred to, are stated to have collected in half an hour nearly forty of these lizards of different sizes, varying from two feet long to three inches. They stated that the island seemed to be swarming with them, and with another lizard called the moko-moko (*Tiliqua zeelandica*). In the day-time these lizards are seen basking themselves in the sun on the bare rocks. Noon is therefore the best time to visit the islands. It is stated that there are four small islands, on two of which Tuateras are found.

I mention this fact in case it should be within the power of any of the Antipodean readers of NATURE to visit these islands, and obtain examples of this reptile. For although the British Museum has a good supply of specimens of it, yet the animal is a great *desideratum* elsewhere, and I believe there are no examples of *Sphenodon* in any of the continental collections.

P. L. S.

NOTES

THE honorary degree of D.C.L. has been conferred, at the recent Commemoration, by the University of Oxford on the following scientific men:—Sir William George Armstrong, C.B.; Sir James Alderson, M.D., President of the Royal College of Physicians; John P. Gassiot, Vice-President of the Royal Society; Charles W. Siemens, F.R.S.; James Fergusson, F.R.S.; Sir J. Kay-Shuttleworth, Bart., the Rev Henry Moseley, M.A., F.R.S., Canon of Bristol; Professor Hermann Helmholtz; George Edward Paget, M.D., President of the General Medical Council; Edward Frankland, F.R.S.; Henry Bence Jones, M.D., F.R.S.; Warren De La Rue, Vice-President of the Royal Society; William Huggins, F.R.S., Secretary to the Royal Astronomical Society. The name of Charles Darwin, F.R.S., would have been included in the foregoing list (as stated in our last number) but he writes that his health is such "that he could not withstand the fatigue and excitement of receiving an honorary degree." We understand that Prof. Helmholtz has also been prevented from attending. There is a rumour that Science would have been even more brilliantly represented if the degree were the simple thing it is often supposed to be. It really stamps, it seems, a judicious mixture of celebrity and orthodoxy; *e.g.*, either much orthodoxy and a little celebrity, or a little orthodoxy and much celebrity, will qualify, but a dash of orthodoxy is *de rigueur*. The *imprimatur*, therefore, is of double value. In the present case, for instance, it is proclaimed to the world that Mr. Darwin, for example, is not only Mr. Darwin, but that Dr. Pusey, and others even more skilled in heresy than he, consider him orthodox. On the whole we should prefer the abolition of tests even here, and one has only to go to Oxford and watch the present scientific activity, the magnificent museums and laboratories which are growing or have grown, to predict that the Oxford of a few years hence will be of the same opinion.

MEETINGS of the Royal Commission on Scientific Instruction and the Advancement of Science have been held at 6, Old Palace Yard, S.W., on the 14th, 15th, 17th, and 21st of this month. Present:—The Duke of Devonshire, K.G.; the Marquis of Lansdowne; Sir John Lubbock, Bart., M.P., F.R.S.; Sir J. P. Kay Shuttleworth, Bart.; Mr. B. Samuelson, M.P.; Dr. Sharpey, Sec., R.S.; Prof. Huxley, F.R.S.; Dr. W. A. Miller, Treas., R.S.; Prof. Stokes, Sec. R.S.; and the Secretary, Mr. J. Norman Lockyer, F.R.S.

MR. E. J. STONE, F.R.S., first assistant at the Greenwich Observatory, has been appointed Astronomer at the Cape of Good Hope. This appointment will be hailed with the liveliest satisfaction by all scientific men, and we may hope that the fine Observatory there may soon take high rank among similar establishments.

THE examiners for honours in the Natural Science School at the University of Oxford, viz., Henry J. S. Smith, Edward Chapman, and Joseph F. Payne, have made the following award:—Class 1. Walter William Fisher, Postmaster of Merton College; Edwin Harding Lendon, Gunsley Exhibitioner, University College; Charles Samuel Taylor, Commoner of Merton College. Class 2. John Fleming Hartley, Commoner of Brasenose College. Class 3. John Richardson Burrow, Thanet Exhibitioner of Queen's College. Class 4. Nil.

WE hear with great satisfaction that the Government of India has ordered the adoption of the metric system of weights and measures.

A NEW Astronomical Observatory has been established by the Government of the Argentine Republic in South America, to be erected at Cordova, about the middle of the continent, on the margin of the Pampas, in lat. $31\frac{1}{2}°$ S. Dr. B. A. Gould has been invited to organise it, and is going out for the special purpose of extending through the southern hemisphere the system of zones, which Bessel and Argelander have already carried from the north pole as far as 30° S. He hopes also to obtain some photometric determinations of the principal southern stars. The undertaking has been instituted and carried out entirely by the Government of the Argentine Republic, at the instance of the President, M. Sarmiento, and of Dr. Avellaneda, the Minister of Public Instruction; but the various scientific institutions of the United States have aided the expedition greatly by loans of important and valuable instruments; and Dr. Gould expresses his obligation to the Coast Survey, the "American Nautical Almanac,"

* See Gould's Monograph of the Trochilidæ, Introduction, p. xxxvi.
† Phil. Trans. 1867, p. 595.

the Washington Observatory, the National Academy of Sciences, and the American Academy of Boston, all of which have afforded valuable assistance in providing him with instruments and equipment. This will be the second public observatory in South America, that at Santiago, in Chile, having been founded in 1851. Efforts are making to provide means for obtaining photographic impressions of some of the more prominent southern clusters of stars, analogous to those taken in the northern hemisphere by Mr. Rutherford; but the success of these efforts is still uncertain. Dr. Gould estimates that three years will suffice to complete the southern zones within the limits which he has assigned to himself. We look forward with the most sanguine hopes to the results of Dr. Gould's labours. In time we may hope to be almost as civilised as the Argentine Republic—almost as anxious to spread the knowledge of Nature.

WE learn from the *Academy* that the Philosophical Faculty of the University of Göttingen has announced for the 11th March, 1873, a prize of 500 thalers in gold, and a second prize of 200 thalers in gold on the Beneke foundation, for the best new determination of the atomic weights of the metals of the earths. The limits of error in the results obtained must be exactly fixed, and the investigation must be accompanied by a complete critical review of the existing scientific material connected with it. In his classical researches in this field, Stas ascertained the combining weights of ten elements, leaving those of five-sixths of the elements more or less unprecisely determined. It has been resolved, therefore, to subject some of the numbers to careful revision, and those attached to the earth-metals have been selected. The dissertation, written in Latin, French, German, or English, and distinguished by a motto, must be deposited with the Dean of the Faculty on or before August 31, 1872.

THE Lecture, next Sunday evening, at St. George's Hall, Langham Place, is on "Cruelty in Relation to Lower Animals," by T. Spencer Cobbold, M.D., F.R.S.

THE Anniversary Meeting of the Society of Arts will be held on Wednesday next, the 29th inst., at four o'clock.

THE indifference of agriculturists to scientific research has been again illustrated by the refusal of the Council of the Royal Agricultural Society to publish an account of the investigations which have established the truth of the old bucolic dogma, that berberries produce rust on wheat growing in their vicinity. There is now no doubt that the berberry-rust and the wheat-rust are two different stages in the genetic cycle of *Puccinia graminis*.

HER Majesty's Commissioners for the International Exhibition of 1871 have resolved to set aside one guinea out of every season ticket sold at three guineas, through the Society of Arts, for the purchase of works of art and industry, out of the exhibition, the same to be circulated throughout the United Kingdom.

THE *Pharmaceutical Journal* announces that a new series will be commenced next month, when it will appear in a new form, and as a weekly publication, the first number to be published on the 2nd of July. The *Pharmaceutical Journal* was originally established by the late Mr. Jacob Bell, as an organ of communication especially devoted to the interests of the Pharmaceutical Society, which was founded at the same time, and it has been published monthly during the last twenty-nine years.

AN industrial and technological museum has been recently formed in Victoria. It is connected with the Gallery of Art and the Public Library at Melbourne, and is governed by the same body of trustees. In the Library there are over 50,000 volumes, and in the Gallery of Art pictures by Goodall, Webb, Graham, Lee, &c., besides several pictures by colonial artists and a very large collection of casts from the antique. Before this museum was formed a Royal Commission had been appointed for promoting industrial instruction, and resulting from this movement we may add, that there are now no less than six schools of design open in Melbourne and the suburbs, with over 600 pupils in attendance.

THE statistics given in M. Bouley's course of lectures on "Madness in Man and Animals" confirm the statement that hot weather is not a cause of *rabies;* out of 302 cases recorded in six years, eighty-nine occurred in the spring from March to May, seventy-four in the summer from June to August, sixty-four in the autumn from September to November, and seventy-five in the winter from December to February. Male animals appear far more subject to the attacks of the disease than female animals. Out of 320 cases of bites from rabid animals, 284 occurred with dogs (male), twenty-six with bitches, five with cats (male and female), and five with wolves (male and female). No instance is recorded of any attack on man by a rabid herbivorous animal. Now that we are approaching the dog-days, we commend these facts to the notice of the chief commissioner of police, and trust we shall have no repetition of the cruel and senseless police regulations as to the muzzling of dogs; to be consistent they should be in force all the year round.

WE learn from the *British Medical Journal* that Miss Garrett has just passed her final examination for the degree of Doctor of Medicine in Paris. Her thesis has been read, and at the same time she received her degree from the Faculty of Medicine. Whatever opinion may be entertained, says our able contemporary, as to the desirability of ladies studying and practising medicine, everyone must admire the indomitable perseverance and pluck which Miss Garrett has shown in overcoming the many obstacles to obtain in the first place the qualification of the Apothecaries' Company in London, and, lastly, the Degree in Medicine of the University of Paris.

MR. CYRUS REDDING, who died recently at a very advanced age will, perhaps, be best known as the author of a "History and Description of Modern Wines," which was first published in 1833, and has passed through several editions, being the standard work on the subject. Among his MSS. he has left a "Wine-book of Europe." Mr. Redding has enjoyed for the last few years a government pension of 75*l.* per annum, which it may be hoped, will be continued to his aged widow.

THE patent for printing photographs by a permanent process known as the Woodbury type, has been purchased by Mr. Vincent Brooks, of Gate Street, Lincoln's Inn Fields, on behalf of a new company.

WE have just seen a bill-head or order to which we think it necessary to call attention. On a scroll at the top is a name which, together with the address, which is on another scroll, we suppress, as we do not wish to assist this person in his advertisements. On other artistic scrolls we find the occupations of the advertiser, dyeing and printing works being set forth on one of them. In the centre is a coat of arms and crest surrounded by a garter, on which is printed *Fellow of the Chemical Society, London.* We have no wish to infer that this gentleman is not a most eminent chemist, but we do most emphatically protest against the membership of a learned society being turned to account for advertising purposes. We hope that the Council will not allow this to continue unnoticed, for nothing could be more damaging to the welfare of a scientific society.

A RECENTLY published part of Baillon's "Histoire des Plantes" contains a monograph of the Papilionaceous section of *Leguminosæ* executed with his usual care and wealth of illustration. We are glad to hear that an English translation of the work is announced.

"MITTHEILUNGEN der Anthropologischen Gesellschaft in Wien," is the title of a periodical which the Anthropological Society of Vienna have begun to publish, with accounts of their own proceedings and papers, of discoveries of ancient remains in tumuli and elsewhere, and papers in which questions in their special pursuit are discussed. Two numbers are out. The first contains an opening address by Rokitansky, and among the contributors we notice the names of F. Müller, Graf Augustus von Breuner, F. von Hauer, and Freiherr von Sacken. Austria is so rich in ethnological varieties and relics that interesting matter sufficient for a monthly periodical must, we should think, be always forthcoming. It will be an acceptable addition to the scientific libraries of this country, and we offer to the society our best wishes for its success.

KARL VON LITTROW'S "Zählung der nördlichen Sterne im Bonner Verzeichnisse nach Grössen" has been reprinted from the Sitzungsberichte der k. Akademie der Wissenchaften. He estimates the number of stars to the sixteenth magnitude (or more exactly to the magnitude 15·8) at 588 millions for the northern hemisphere, and about 1,200 millions for the whole heavens.

"NOTES AND QUERIES for China and Japan," which has just entered on a new series, is a monthly medium of inter-communication for professional and literary men, missionaries, and residents in the East generally, conducted by C. Langdon Davies. In the number just received we find an article on the Fung tree (*Liquidambar formosana* Hance), the leaves of which afford food to a species of caterpillar (termed the wild silkworm), which produces an inferior kind of silk.

THE "Proceedings of the Bath Natural History Society and Antiquarian Field Club" for 1870, are mainly occupied, as they should be, by papers of local interest, which well illustrate the great wealth of the districts to the naturalist, whether geologist, botanist, or antiquarian. Thus we have "The Mammalia and other Remains from Drift Deposits in the Bath Basin," by C. Moore, with copious lists of organic remains found in the pre-historic alluvium and gravel deposits; "Remarks on some of the Fungi met with in the neighbourhood of Bath," by C. E Broome (edible fungus hunting seems to be a favourite pursuit with local field-clubs since the Woolhope naturalists set the example); "Notes on the Chapel and Hospital of St. Mary Magdalene," by Rev. W. Stokes Shaw; and "Notes on a pair of Celtic Spoons found near Weston, Bath, in 1866," by Rev. Preb. Scarth. Of articles of a less local character, we have "Chemical Geology," by Charles Ekin, containing a sketch of recent spectroscopic researches; and a pleasant gossiping paper, by Rev. H. N. Ellacombe, on "The common English names of Plants."

A REPORT from Mr. R. S. J. Ellery, Government Astronomer, on the subject of the Equatorial Telescope at Melbourne, has been received by the Victorian Legislative Council. The telescope arrived in November 1868; its erection at the Observatory was commenced early in July 1869, and the building for its protection was not finished till the 1st June, the final fitting up of the telescope being completed early in July. Observations were attempted as early as April last year, but the telescope was not in working order till the middle of August, since which date observation has progressed more or less satisfactorily. The principal work has consisted in examination and mapping of nebulæ, but the very unfavourable weather throughout almost the whole season has prevented much progress of other work. Positive observations have been made of Winnecke's periodical comet. With respect to spectroscopic observations, Mr. Le Sueur, the astronomer in charge, says—The spectroscope furnished by Mr. Grubb has already proved of much service for nebulæ work. For star work, so far as I can at present judge, it is unsuitable; nevertheless, a very important observation has lately been made therewith, showing that the spectrum of the principal η Argo is crossed into bright lines. In his report to the Board of Visitors in April last, Mr. Ellery referred to the construction of the telescope, but could not at that time speak of its performance or capabilities; but during the several months' use since then Mr. Le Sueur has tested its performance most carefully, and although he has had no prior experience with reflecting telescopes of such dimensions as this, he has been enabled from frequent observations to form a sound opinion of its powers. With the large mirror first used the telescope certainly did not perform so satisfactorily as could be desired, and making all allowances for atmospheric disturbances, the definition was never good; but with the other mirror (supposed B) it became very much better, and Mr. Le Sueur speaks of its performance now as far more satisfactory. The building for the protection of the telescope is in most respects satisfactory. There are several arrangements and appliances yet required, before the telescope can be said to be properly provided, among which are more convenient observing seats, drawing stands, and the erection of a platform outside the telescope room for photographic operations. Some of these are already in progress, and, should sufficient means be available, will soon be completed.

IN the recently issued Colonial Blue Book ("Reports on the state of H.M. Colonial Possessions," part I., West Indies), the Governor of Jamaica reports as follows:—"The cinchona plantation is a most interesting experiment, which may now be pronounced a complete success. Cinchona plants were first received here in 1866. By the close of 1867 the number of young plants had so much increased, that it became necessary to provide land for their final establishment on a planter's scale. Six hundred acres of virgin forest in Blue Mountain were acquired early in the year, and were set apart for the purposes of a cinchona plantation, for which the place is in every way admirably suited. The elevation above the sea ranges from 4,000 to 6,000 feet. It is well watered, has the best aspects, and possesses a soil reported to be admirably suited to the requirements of the cinchona. Fifty acres were cleared, of which forty were filled with cinchonas in the course of the year; about 20,000 plants of five different species were planted. By the latest accounts all of these were in full vigour, and the plantation must by this time be doubled in extent. The plants have stood one of the dryest seasons that has ever been remembered on Blue Mountain, without suffering in the least. There is now no doubt that the cinchona can be successfully reared in Jamaica." The plants for sale, deliverable in the spring of 1869, were applied for to the number of about 2,000 only; but Sir James Grant expresses the hope that with the growth of the plants a spirit of intelligent enterprise will grow amongst the proprietors of mountain wastes, sufficient to induce them to turn some attention to such a highly promising experiment.

THE *Journal of the Franklin Institute* describes a new explosive which has been invented by Mr. Noble, the inventor of nitro-glycerine and dymanite, and which he calls dualine. It consists principally of nitrate of ammonia and very fine saw-dust which has been acted on by nitro-sulphuric acid. It is said not to be decomposed by accidental contact with acids, and will not congeal or lose any of its properties during cold or hot weather. Its explosion does not produce any noxious gases, and it will burn in the open air without exploding.

THE *Architect* states that the North-Eastern Railway Company is forming a new line between Gilling and Helmsley, which passes through the Caulkless spur of the Hambletons, in a deep cutting near Stonegrave. Here, at a depth of nearly thirty feet, a large chamber in the Oolite rock has been discovered. It is as large as an ordinary room, and has three openings from it. The cave is on the same horizon as the famous Kirkdale cave.

MR. MELDRUM ON THE ORIGIN OF STORMS IN THE BAY OF BENGAL *

THE writer commenced by observing that in various papers published during the last ten years, he had stated, as the result of an examination of a large body of observations, that the tropical cyclones of the Indian Ocean, south of the Equator, originated between two contrary streams of air, viz., the N.W. monsoon and the S.E. trade-wind; and, in a paper read on the 10th of November last, he remarked that what had been found to hold good in that part of the ocean might be found to do so generally. As the observations collected by the Society only referred to the Indian Ocean, he could not directly test the matter with regard to the cyclones of other parts of the world. But cyclones also occurred in the Indian Ocean, north of the Equator, and as the Society possessed observations which had been taken there, he proposed to examine the records with a view of ascertaining whether these cyclones were formed, as he believed those south of the Equator were, between two oppositely directed currents of air which had pre-existed. It was to that point alone that he wished to direct attention at present. How the barometric depression in the heart of a cyclone was formed, whether owing to an ascending current, to condensation of vapour, or to other causes, why the air moved more or less round a central area in a particular direction, and why the cyclone had a progressive movement, were subjects upon which he would not then touch; for the question of the existence or non-existence of opposite winds, previously to the formation of the cyclone, had, in his opinion, an important bearing upon all the others, and should therefore be taken up first.

The cyclones of the Indian Ocean, south of the Equator, as was well known, took place during six months of the year, viz., November to May. During that period the N.W. monsoon prevailed from near the Equator to 10° or 15° S., sometimes stretching as far south as the tropic. Still farther south the S.E. trade-wind prevailed. The line or belt separating the two winds often ran obliquely across the ocean from 18° S., near Madagascar, towards the Straits of Sunda. It was in that belt of comparatively low barometer, calms, and variables, that the tropical cyclones of the Indian Ocean, south of the Equator, were formed. The N.W. monsoon was a continuation of the N.E. trade-wind of the northern hemisphere. This might be seen on almost any day from November to April or May, by laying down the directions of the wind at a sufficient number of points; and the daily charts which had been prepared for various periods showed it very clearly. On examining those for February, 1861, for example, which had lately been lithographed, it would be seen that the N.E. trade-wind prevailed over the Bay of Bengal and the Arabian Sea, that as it approached the Equator it became more northerly, and after crossing the Equator into the southern hemisphere it became the N.W. monsoon. The southern limits of the N.W. monsoon, and the northern limits of the S.E. trade, or, in other words, the position of the belt of variables between them, moved backwards and forwards according to the season. It was farthest S. when the southern hemisphere was warmest. As the temperature decreased, towards the end of March, this belt retreated northwards with the sun, came up to the Equator, and crossed it into the northern hemisphere. In whatever part, N. or S. of the Equator, the belt of calms existed, the prevailing winds on either side of it were from opposite directions. When it was S. of the Equator, the prevailing wind to the southward of it was from the S.E. or E. (the S.E. trade), and to the northward of it from N.W. or W. (the N.W. monsoon.) The latter extended at least as far N. as the Equator, and the N.E. trade, of which it was the continuation, prevailed over the Bay of Bengal. The former at the same time prevailed as far south as the parallel of 30° or 40° S. When the belt of calms was N. of the Equator, the prevailing wind to the S. of it was from S.W. or West, and to the N. of it from N.E. or E. The former was the S.W. monsoon, and the latter the N.E. trade-wind. In July and August, when the belt was far N., the S.W. monsoon prevailed over the whole of the Bay of Bengal, and was a continuation of the S.E. trade-wind, just as the N.W. monsoon in February and March was a continuation of the N.E. trade-wind. The belt of calms followed the sun, moving from one tropic to the other, and often passing them. Hence, when it was at its northernmost limit, the S.W. monsoon swept over the Bay of Bengal, and when at its southernmost limit, the N.E. trade-wind did so. But at certain seasons, when the belt of calms stretched across the Bay, the S.W. monsoon blew over one part of it and the N.E. trade over the other.

As, then, observation had shown that the tropical cyclones of the Indian Ocean, south of the Equator, were formed in the belt of calms between the N.W. monsoon and the S.E. trade-wind, and nowhere else, there was at least a presumption that the cyclones of the Bay of Bengal were also formed in that belt, at those seasons when it stretched across the Bay, and separated the N.E. trade wind from the S.W. monsoon; and this presumption was strengthened by the fact that most, if not all, of the cyclones that occurred there, did so at the change of the monsoons; that is, when two contrary winds prevailed in the Bay, and were more or less in conflict.

These general considerations rendered it possible, if not probable, that the cyclones of the Bay of Bengal were formed between two contrary and pre-existing winds. But that was not sufficient. It was necessary to bring the matter to the test of facts; and this could only be done by examining the observations taken in particular storms. He would begin with the destructive storm which visited Calcutta on the 5th October, 1864. On the 12th September in that year, the ship *Furness Abbey*, Capt. Roddock, in 19° 08′ N. and 88° 55′ E., had a fresh breeze from W.S.W. and S.W., and she carried that wind to 4° 44′ N. and 92° 38′ E. on the 21st. The *Victoria Nyanza*, Capt. A. J. Reed, had a strong wind from S.W. on the 21st. Sept., in 18° 17′ N., and 87° 46′ E., and she carried that wind to 0° 45′ S. and 91° 02′ E. on the 25th. The French barque *Leonide*, Capt. Martin, outward bound, approached the Equator with the S.E. trade-wind, which gradually veered to S. and S.S.W., and from 1° 59′ N. and 84 05′ E. on the 6th, to 19° 29′ N. and 88° 27′ E. on the 13th Sept., she had fresh and strong winds from the S.W. Moreover, he had prepared a chart for the 21st September, which showed that on that day eleven vessels, from the Equator to 20° N., in the Bay of Bengal, had the wind from W.S.W. and S.W., in moderate and fresh breezes. These observations proved that up to that date the S.W. monsoon prevailed in the Bay. But a change was at hand. On the 26th September, the wind in the northern part of the Bay was light from the northward, and in the southern part moderate from westward. On the 29th September there was a strong breeze blowing from the W.S.W., with squally rainy weather from near the Equator to at least 10° N., whilst in the northern part of the Bay the wind was light from the N. On the 2nd Oct. there were signs of a cyclone. To the S.W. of the Nicobars a strong breeze was blowing from the W.S.W., with squally rainy weather. In the Gulf of Martaban there was a gale from the S.E., with much rain and lightning. To the S.E. of Coringa the wind was increasing from N.E., with thunder and lightning. On the 3rd and 4th there was strong evidence of the existence of two contrary winds, the one from N.E. and the other from S.W., with a cyclone between them; but the S.W. wind was apparently overcoming the other. On the 5th, when the storm was at Calcutta, the S.W. wind had established itself over the greater part of the Bay. But this was only a temporary victory, for by the 8th the N.E. wind was blowing fresh over the northern portion of the Bay. The S.W. wind, however, still prevailed farther south. By noon on the 15th the N.E. wind prevailed over the whole Bay.

He had not been able to examine the subject farther, but would return to it at next meeting. In the meantime, he thought that the evidence adduced went to show that the storm originated in the belt of calms between the N.E. trade and the S.W. monsoon.

* Paper read before the Meteorological Society of Mauritius, March 24, 1870.

CHEMISTRY

Specific Gravities of Aqueous Solutions

IN Gerlach's *Sammlung der specifischen Gewichte wässeriger Lösungen* is a large amount of information which will prove of great use to manufacturers and others who have to deal with aqueous solutions of acids, alkalies, and salts.

The first table consists of nine columns marked with letters. In column A are placed the formulæ and combining weights, according to the old notation, of the bodies dissolved, both in the anhydrous and hydrated condition. Column B contains the weight of the dissolved body in the hydrated condition, or with water of crystallisation, which is present in 100 parts by weight of the solution. C shows the weight of the dissolved substance in the anhydrous condition. The numbers in this column may be calculated from those in the second column by multiplying by the combining weight of the anhydrous and dividing by that of the hydrated substance. Column D gives the weight of the body in the dry state, which is dissolved in 100 parts of water, and is calculated by multiplying the numbers in column C by 100 and dividing by 100—C :—

$$D = \frac{C \times 100}{100 - C}$$

Column E contains the number of atoms of the anhydrous salt in 100 parts by weight of water. The expression *atom* is here synonymous with *equivalent*. The atom of hydrogen is taken at $\frac{1}{100}$:—

$$E = \frac{D \times 100}{A \text{ (anhydrous)}}$$

F gives the volume of the solution; 100 parts by weight of the water of the solution being taken as 100 volumes :—

$$F = \frac{D \times 100}{\text{spec. grav.}}$$

G indicates the specific gravities of the solutions. H contains the volumeter degrees, according to the scale of Guy Lussac, which correspond to the specific gravities :—

$$H = \frac{100}{G}$$

In column I are found the names of the observers, the temperature, and the references to the sources from which the numbers were obtained.

In this first table we find the various numbers corresponding to solutions of different states of concentration. In some cases the numbers are given for solutions at intervals of 1 per cent. of the salt, in others of 5 per cent., and in others of 10. The table commences with caustic alkalies, including ammonia, potash, and soda. Then follow the potassic and sodic carbonates, the chlorides of ammonium, potassium, sodium, lithium, aluminium, magnesium, calcium, strontium, barium, cadmium, and zinc, and stannous and stannic chlorides. The next section contains the bromides of potassium, sodium, lithium, magnesium, calcium, strontium, barium, cadmium, and zinc; whilst under the iodine compounds we find potassic, sodic, lithic, magnesic, calcic, strontic, baric, cadmic, and zincic iodides. Next comes sodic hyposulphate, and the sulphates of ammonium, potassium, sodium, manganese, and iron, the double sulphate of iron and ammonium, magnesic sulphate, potassia-magnesic sulphate, and the sulphates of zinc and copper. This series is followed by sections containing potassic chromate and bichromate, hydric disodic, and trisodic phosphates; hydric disodic, and trisodic arseniates; nitrates of potassium, sodium, magnesium, strontium, barium, and lead; chlorates of potassium and sodium; bromates of potassium and sodium, iodates of potassium and sodium; potassic ferrocyanide and ferricyanide; plumbic acetate; potassic and sodic tartrate; and Rochelle salt. The remainder of the table is devoted to the acids, and includes the following:—Hydrochloric, sulphuric, sulphurous, phosphoric, arsenic, nitric, acetic, tartaric, and citric.

After the table follows a chapter discussing the relations existing between the specific gravities of equally concentrated solutions; and three others: On the change of volume produced by solution of salts; on the change of volume produced on the dilution of aqueous solutions; and on the change of volume produced by mixing different solutions.

The pamphlet concludes with a table extending over 19 pages, and containing the specific gravities of solutions, in most cases from 1 per cent. to nearly the point of saturation, though in some few instances they are given at every 5 per cent. This table gives, in addition to those of the substances above enumerated, the specific gravities of solutions of sugar and alcohol. Dr. Gerlach deserves the thanks of chemists and chemical manufacturers for undertaking the tedious labour of collecting and arranging in tables the large series of numbers which are found in this pamphlet.

SCIENTIFIC SERIALS

THE *American Journal of Science* for May, 1870, contains a good article "On a simple method of Avoiding Observations of Temperature and Pressure in Gas Analyses," by Wolcott Gibbs, M.D., Professor in Harvard University.

In absolute determinations of nitrogen and other gases, accurate observations of temperature and pressure are, in the ordinary methods of analysis, necessary, and when made require subsequent calculations which, when the analyses are numerous, become rather tedious. By the following simple method these observations may be altogether dispensed with, and the true weight or the reduced volume of the observed gas, obtained at once by a single arithmetical operation.

"A graduated tube, holding about 150 cubic centimetres, is filled with mercury, and inverted into a mercury trough. Two thirds or three fourths of the mercury are then displaced by air, care being taken to allow the walls of the tube to be slightly moist, so as to saturate the air. This tube may be called the companion tube; the volume of air which it contains must be carefully determined in the usual manner by five or six separate observations, taking into account, of course, all the circumstances of temperature and pressure. The mean of the reduced volumes is then to be found, and forms a constant quantity. The gas to be measured is transferred from the receiver in which it is collected, into a (moist) eudiometer tube, which is then suspended by the side of the companion tube, and in the same trough or cistern. Both tubes being supported by cords passing over pulleys, it is easy to bring the level of the mercury in the two tubes to an exact coincidence. The pressure on the gas is then the same in each tube. The temperature is also the same, as the tubes hang side by side in the room set apart for gas analyses, and are equally affected by any thermometric change. It is then only necessary to read off the volumes of the gas in the two tubes to have all the data necessary for calculating the weight of the gas to be measured. . . . . As the observed volume of the air in the companion tube is to the observed volume of the gas in the measuring tube, so is the reduced volume of the air in the first—previously determined as above—to the reduced volume of the gas to be measured. This method of course applies to the reduction of any gaseous mixture whatever to the normal pressure and temperature. . . . . In practice, a companion tube filled with mercury will last with a little care for a very long time. Even when filled with water I have found that excellent results may be obtained, and that the tube will last for some weeks. Williamson and Russell, in their processes for gas analysis, have employed a companion tube for bringing a gas to be measured to a constant pressure, but the application made above is, I believe, wholly new."

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 19.—"A Ninth Memoir on Quantics." By Prof. Cayley.

It was shown not long ago by Prof. Gordan that the number of the irreducible covariants of a binary quantic of any order is finite (see his memoir "Beweis das jede Covariante und Invariante einer binären Form eine ganze Function mit numerischen Coefficienten einer endlichen Anzahl solcher Formen ist," Crelle, t. 69 (1869), memoir dated 8th June 1868), and in particular that for a binary quantic the number of irreducible covariants (including the quantic and the invariants) is = 23, and that for a binary sextic the number is = 26. From the theory given in my "Second Memoir on Quantics," *Phil. Trans.* 1856, I derived the conclusion, which as it now appears was erroneous, that for a binary quintic the number of irreducible covariants was infinite. The theory requires, in fact, a modification, by reason that certain linear relations, which I had assumed to be independent, are really not independent, but, on the contrary, linearly connected together: the interconnection in question does not occur in regard to the quadric, cubic, or quartic; and for these cases respectively the theory is true as it stands; for the quintic the interconnection first presents itself in regard to the degree 8 in the coefficients, and order 14 in the variables; viz., the theory gives correctly the number of covariants of any degree not exceeding 7, and also those of the degree 8, and order less than 14; but for the order 14 the theory as it stands gives a non-existent irreducible covariant

$(a, \ldots)^3(x, y)^{14}$; viz., we have, according to the theory, $5 = (10-6)+1$, that is, of the form in question there are 10 composite covariants connected by 6 syzygies, and therefore equivalent to $10-6=4$ asyzygetic covariants; but the number of asyzygetic covariants being $=5$, there is left, according to the theory, 1 irreducible covariant of the form in question. The fact is that the 6 syzygies being interconnected and equivalent to 5 independent syzygies only, the composite covariants are equivalent to $10-5=5$, the full number of the asyzygetic covariants. And similarly the theory as it stands gives a non-existent irreducible covariant $(a, \ldots)^8(x, y)^{20}$. The theory being thus in error, by reason that it omits to take account of the interconnection of the syzygies, there is no difficulty in conceiving that the effect is the introduction of an infinite series of non-existent irreducible covariants, which, when the error is corrected, will disappear, and there will be left only a finite series of irreducible covariants. Although I am not able to make this correction in a general manner so as to show from the theory that the number of the irreducible covariants is finite, and so to present the theory in a complete form, it nevertheless appears that the theory can be made to accord with the facts; and I reproduce the theory, as well to show that this is so as to exhibit certain new formulæ which appear to me to place the theory in its true light. I remark that although I have in my Second Memoir considered the question of finding the number of irreducible covariants of a given degree θ in the coefficients but of any order whatever in the variables, the better course is to separate these according to their order in the variables, and so consider the question of finding the number of the irreducible covariants of a given degree θ in the coefficients, and of a given order μ in the variables. This is, of course, what has to be done for the enumeration of the irreducible covariants of a given quantic; and what is done completely for the quadric, the cubic, and the quartic, and for the quintic up to the degree 6 in my Eighth Memoir (*Phil. Trans.* 1867.) The new formulæ exhibit this separation; thus (Second Memoir, No. 49), writing a instead of x we have for the quadric the expression $\frac{1}{(1-a)\ (1-a^2)}$, showing that we have irreducible covariants of the degrees 1 and 2 respectively, viz., the quadric itself, and the discriminant: the new expression is $\frac{1}{(1-ax^2)\ (1-a^2)}$, showing that the covariants in question are of the actual forms $(a, \ldots \between x, y)^2$ and $(a, \ldots)^2$ respectively. Similarly for the cubic, instead of the expression No. 55, $\frac{1-a^6}{(1-a)(1-a^2)(1-a^3)(1-a^4)}$, we have $\frac{1-a^6x^6}{(1-ax^3)(1-a^2x^2)(1-a^3x^3)(1-a^4)}$, exhibiting the irreducible covariants of the forms $(a, \ldots \between x, y)^3$, $(a, \ldots)^2 (x, y)^2$, $(a \ldots)^3 (x, y)^3$, and $(a, \ldots)^4$, connected by a syzygy of the form $(a, \ldots)^6 (x, y)^6$; and the like for quantics of a higher order.

In the present Ninth Memoir I give the last-mentioned formulæ; I carry on the theory of the quintic, extending the Table No. 82 of the Eighth Memoir up to the degree 8, calculating all the syzygies, and thus establishing the interconnections, in virtue of which it appears that there are really no irreducible covariants of the forms $(a, \ldots)^8(x, y)^{14}$, and $(a, \ldots^8 \between x, y)^{20}$. I reproduce in part Prof. Gordan's theory so far as it applies to the quintic; and I give the expressions of such of the 23 covariants as are not given in my former memoirs; these last were calculated for me by Mr. W. Barrett Davis, by the aid of a grant from the Donation Fund at the disposal of the Royal Society. The paragraphs of the present memoir are numbered consecutively with those of the former memoirs on Quantics.

"On the Chemical Activity of Nitrates." By Edmund J. Mills, D. Sc.

"On the relative Duration of the component parts of the Radial Sphygmograph Trace in Health." By A. H. Garrod.

Anthropological Society, May 19.—Dr. Berthold Seemann, V.P., in the chair. Mr. Henry F. Chorley read a paper on "Race in Music." The author, after remarking on the vast range of the subject for treatment in the compass of a single paper, proceeded to point out the difficulties that stood in the way of determining what is and what is not truly national music, one great difficulty consisting in the inaccuracies of notation. Notation being comparatively a modern art and the only means by which musical ideas can be transmitted, we are very much in the dark as to the advance made by the ancients in the art of music. Confining himself chiefly to the modern development of music, Mr. Chorley argued that new and original melody is far less common than is generally supposed. By the simple variation of *tempo*, implying some change in accentuation, a melody can be so entirely transformed as to lose its original character. Genuine, fresh, national music is, again, comparatively rare, and its character has always been most marked whenever intercourse has been the most restricted. Passing from the more limited subject of national music to the broader question of race-elements in music, the author illustrated the great distinction which exists between the Asiatic and the European development of the art; in the former it is confined to rhythm, and seldom includes beauty of sound or symmetry of form. In strong contrast to the Oriental ideas of music were cited those of the north of Europe, viz., Norway, Sweden, Denmark, and Russia. In the opinion of the author those people take the highest place as melodists. It should as a fact be noted that with few exceptions those northern airs are in minor keys, which might be taken as an expression of, rather than a protest against, the gloom of the climate and scenery, were it not that the same characteristic largely obtains among inhabitants of the torrid zone. The sense of musical rhythm seems as distinctly marked among different peoples as varieties of physiognomy; for instance, the Peninsular melodies are only characteristic when they are in triple time, the airs in common time being essentially mawkish and pointless, owing such individuality as they have to the sleepy, voluptuous delivery of the executant. On the other hand, the music of France lies essentially in the direction of squared music towards what is piquant as distinct from what is undulating. In treating of the subject of Race in Music the author could not but draw attention to a phenomenon which is of universal recurrence, namely, the demarcation not merely of race but also of sex in the art, be its stages of culture or civilisation ever so primitive, ever so mature. The absence of musical inventive genius in woman is most curious and inexplicable, and offers another signal illustration of the contradictions and inconsistencies which mark music beyond any other art. While women have achieved distinction and often great success in literature, painting, sculpture, architecture, and science, and while they are unsurpassed as interpreters of the drama and of the art of music, not a solitary female composer of originality or even of repute is known to the historical or critical observer. Mr. Dannreuther illustrated the paper by numerous examples on the pianoforte.

Entomological Society, June 6.—Mr. A. R. Wallace, president, in the chair. Mr. F. V. Jacques, of Bristol, was elected a member. A collection of insects sent to the Society by Mr. Henry Ansell, from Kinsembo, S.W. coast of Africa, was exhibited; and another collection from Tugela, Natal, was exhibited by Mr. W. Warwick King. Living specimens of *Ateuchus*, from Venice, were shown by Mr. S. Stevens; and a gynaniromorphous *Brachycentrus*, from Cheshunt, was exhibited by Mr. M'Lachlan. Communications were made by Major Munn, on the Honey-Bee, by Mr. A. G. Butler, on the possible identity of *Argynnis Niobe* with *A. Adippe*, and by Mr. G. R. Crotch on the Genera of *Coleoptera* studied chronologically (part 2, from 1802 to 1821.)

Ethnological Society, June 7.—Dr. A. Campbell, V.P., in the chair. R. H. Tiddeman, B.A., F.G.S., was announced as a new member. Professor Huxley, LL.D., F.RS., President, read a paper "On the chief modifications of mankind, and their geographical distribution." After pointing out those physical characters which are of the greatest value in distinguishing the several modifications—such as colour, character of hair, and form of skull—the author proceeded to describe five distinct types of mankind: 1. The *Australioid*, with slender limbs, dark brown skin, black wavy hair, strong brow-ridges, and long skull; this type is found throughout Australia among the hill tribes of the Dekhan in India, and formerly in the Valley of the Nile. 2. The *Negroid*, with dark skin, black frizzled hair, and long skull; a group which includes the Negroes and Bushmen of Africa, and the Negritos of New Guinea, Tasmania, &c. 3. The *Xanthochroic*, with fair skin and blue eyes, distributed through Iceland, Eastern Britain, Scandinavia, North and Central Germany, and extending through Eastern Europe into Asia, as far as North-west India, and found also in the North of Africa. 4. The *Melanochroic*, a type with dark complexion, occupying an area situated between the Xanthochroic and Australioid peoples; and 5. The *Mongoloid*, a large and somewhat ill-defined group extending throughout Central and Northern Asia, the two Americas, and Polynesia. The paper was illustrated by a large coloured map, showing the distribution of these five groups and their subdivisions. Among those who took part in the subsequent discussion were Mr. George Campbell, Mr. A. R. Wallace, Mr. E. G. Squier, Dr. Ray, Mr. Luke Burke, and Mr. Dardy.—Mr. Squier exhibited a large collection of drawings, plans, and photographs of localities of interest in Peru.

Zoological Society, June 9.—George Busk, V.P., in the chair. The Secretary read some notices of the principal additions to the Society's menagerie during the month of May, and called particular attention to a deer sent home from Singapore by order of H.R.H. the Duke of Edinburgh. This animal appeared to belong to a new species, and was proposed to be called *Cervus alfredi*.—Professor Newton, V.P., exhibited a series of skins of the large falcon found in Alaska and sent to this country for examination by the Smithsonian Institution, and referred them to the *Falco islandicus* of Gmelin.—Mr. Gould exhibited and made remarks upon some skins of British water-ouzels.—Mr. R. Swinhoe read a series of zoological notes made during a journey from Canton to Peking and Kalgan. Mr. Swinhoe's remarks contained descriptions of several new species of mammals and birds, amongst which were a new hedgehog, proposed to be called *Erinaceus dealbatus*, and a new species of dwarf swan, for which the name *Cygnus davidis*, after M. le Père David, its discoverer, was proposed.—Mr. R. Swinhoe also read a paper containing notes on certain reptiles and batrachians collected in various parts of China.—Mr. R. B. Sharpe read a paper on the Ornithology of Madagascar, based upon a collection recently formed by Mr. A. Crossley, in the neighbourhood of Noce Vola, in the north-western portion of the island. Two new species were discriminated, and proposed to be called *Ceblepyris major* and *Corethrura insularis*. Two species—viz., *Bernieria crossleyi* of Grandidier, and *Ellisia madagascariensis* of Hartlaub—were likewise generically separated, under the respective names of *Mystacornis* and *Oxylabes*.—Dr. John Hawkes, F.Z.S., communicated a note on a case of *hernia ventriculi* in a common canary.—Mr. D. G. Elliot exhibited and pointed out the characters of two new species of pheasants from the province of Yarkand, proposed to be called *Phasianus shawii* and *P. insignis*; also a well-marked permanent variety of *P. torquatus* from the Island of Formosa, proposed to be called *P. formosanus*. Mr. Elliot also made remarks on the affinities of the known species of true *Phasianus*, and pointed out their geographical distribution.—A communication was read from Mr. A. Sanders, F.Z.S., containing notes on the myology of a Geckoid lizard, *Platydactylus japonicus*.—A communication was read from Mr. Gerard Krefft, C.M.Z.S., of Sydney, containing a preliminary account of the skeleton of a rare whale, probably identical with *Dioplodon sechellensis*, recently obtained in the Australian seas, near Lord Howe's Island.—Messrs. Sclater and Salvin communicated a synopsis of the birds of the family of *Cracidæ*. The authors proposed to divide this family into three sub-families—the *Cracinæ*, *Penolopinæ*, and *Oreophasidinæ*. Of the first of these twelve species were recognised, and of the second thirty-eight, while the third contained only one representative. One species of Guan was described as new, and proposed to be called *Ortalida erythroptera*.—A communication was read from Professor Barboza du Bocage, F.M.Z.S., containing a description of the young of *Pelecanus sharpii*.—Dr. A. Günther communicated an account of the species of tailless batrachians, recently added to the collection of the British Museum, amongst which was a new diminutive frog, recently discovered by Dr. Cunningham in Fuegia, and proposed to be called *Nannophryne variegata*.—Dr. J. Murie read a paper on the anatomy and osteology of the Saiga (*Saiga tartarica*), founded on examples of this mammal that had lived in the Society's Gardens. The conclusions arrived at by the author as to the systematic position of the Saiga were, that this animal cannot be well included in any of the subdivisions of the ruminants hitherto established, but constitutes a form intermediate between the sheep and the antelope.

Victoria Institute, April 25.—Rev. Dr. Thornton, vice-president, in the chair. A paper was read on "Comparative Psychology," by Mr. E. J. Worshead. The following gentlemen took part in the discussion:—Rev. C. A. Row, Rev. J. B. Ouran, Dr. C. Haughton, Mr. Reddie, Rev. Sir S. Marsh, Rev. C. Graham, and the chairman.

Brighton and Sussex Natural History Society, June 9.—Mr. Sewell, vice-president, in the chair. A paper on Diptera and their Wings, by Mr. Peake, was read, in the absence of that gentleman, by Mr. Wonfor, Hon. Sec. While wings are common to the whole order of insects, the Diptera consist entirely of two-winged flies; but instead of a second or hinder pair, they have little thread-like bodies, terminated by knobs and called *halteres*, originally considered balancers, supposed now by some to be *olfactory* organs and by others organs of *hearing*. From many points of resemblance he thought they were analogous to the hind-wings of insects, and that at present their special use had not been ascertained. Besides the halteres they had also winglets (*alulæ*) which were thought to be only appendages to the fore-wings. Among the Diptera three classes of fliers were found, differing in the form of their bodies and shape of their wings; first, the slender flies, such as gnats, having long bodies, narrow wings, and long legs, but without winglets; secondly, those whose bodies, though slender, are more weighty, as the *Asilidæ*, having larger bodies, shorter legs, and very minute winglets; lastly, those like the house-fly, with short, thick, and often very heavy bodies, furnished with proportionate wings, shorter legs, and conspicuous winglets. From these circumstances it might be inferred that the long legs of the light-bodied flies acted as rudders, while the winglets of the heavier bodied flies assisted the wings in flying. The wings might be described as transparent membranous organs, consisting of two laminæ united by veins or nervures, and upon their arrangement and the form of the antennæ the distinguishing characters of the Diptera were formed. The several parts of the wings and nervures and their differences, as seen in the great groups *Nemocera* and *Brachycera*, were next pointed out, and the paper illustrated by drawings and microscopical preparations of wings.

TRURO

Royal Institution of Cornwall, May 17.—The annual meeting of this society was held in the Council-room, Truro, Mr. J. Henwood, F.R.S., president, in the chair. Mr. H. M. Whitley read a paper contributed by Sir. F. M. Williams, M.P.: "Recent Observations on the Subterranean Temperature of Clifford Amalgamated Mines." This gave the result of various observations made during the past fifty years, and, finally, those made by Captain Gilbert previous to ceasing the deep workings some weeks since. Then at 224 fathom level, being 279 fathoms from the surface, the highest temperature recorded was 123°·5; and at 245 fathom level, or 300 fathoms from the surface, the highest was 125°.

Mr. W. Pengelly read a paper, entitled "Notes on the Archæology and Geology of Devon and Cornwall." A difficulty formerly existed in relation to the Devonian series of rocks, for while in the northern part of the area over which it extended there were found fish, in the south there were only sponges and mollusks. The late Mr. Jonathan Couch discovered in 1843 some fossils which he thought fish, but which Professor McCoy in 1857 pronounced to be sponges. The matter dropped till in 1857 he himself submitted to Mr. W. H. Baily a fossil found at Hannafore point, near Looe, and it, with a number of the same kind collected, were pronounced, on the authority of Mr. Simmons and Professor Huxley, to be ichthyolitic. The next point to which he specially wished to direct attention was the rock joints, of which they had two series, one running east and west, and the other north and south, and of which the one that crossed the other was naturally the more recent. Of the age of these joints few indications had been observed. At the eastern shore of Torbay, however, where both these systems were to be observed, it was evident that they were in existence before the close of the New Red Sandstone era, because their fissures were filled with dykes of that rock. The east and west dykes were faulted and traversed by veins of carbonate of lime, which came up on either side to the north and south dykes, but did not cross them. This showed that a considerable time must have elapsed after the formation of the first system of joints before the second. He would commend this subject to the geologists of the county. Next he would refer to the lower Silurian fossils of the Dodman district. At Budleigh Salterton there was a remarkable collection of quartzite pebbles which contained fossils, of which the analogues were to be found in the rocks of Normandy. However, he objected to being beholden to Normandy if he could trace the pebbles to a source nearer home; and he should be delighted if some energetic young Cornishman would devote himself to the elucidation of these quartzite pebbles. Thirdly, whence were the flints on our western strand derived? There was no deposit of flints to the south of the Teign; the course of the shingle could be traced along the coast from the west to the east; and yet there was an abundance of flints, not only in the present beaches all round Cornwall, but in the raised beaches. It would be a comparatively easy but valuable task to ascertain the relative abundance of flints at various points. It would be of still more value if any one would dredge in the Channel, and ascertain whether there were any submarine outliers of gravel from which the flints could be derived. Lastly, he would suggest an inquiry into the megalithic monuments of Cornwall. The origin of the "Hurlers" at Liskeard and the "Merry Maidens" at Penzance was unknown, and it would be interesting to collect anything relating to them which tradition yet retained.

CAMBRIDGE

Philosophical Society, May 30.—The president (Professor Cayley) in the chair. New Fellow elected, F. S. Barff, M.A., Christ's College. Communications made to the Society.—1. By Professor Miller, F.R.S.: On the Invention of the Camera Lucida by Wollaston. 2. By Mr. H. G. Seeley, F.G.S. (1) On the Frontal Bone in the Ornithosauria; with additional evidence of the structure of the hand in Pterodactyles from the Cambridge Upper Greensand. (2) Note on a new species of Plesiosaurus from the Portland Limestone.

DUBLIN

Natural History Society, June 1.—W. Andrews, M.R.I.A., in the chair. Dr. A. W. Foot read some notes on the different insects captured by him during the present spring. He remarked on the lateness of the season and on the paucity of insects coming to sugar; and in giving a list of insects taken at Kilkenny, expressed the hope that a large number of local collections would be made throughout Ireland, stating that if such were sent to the Museum of the Royal Dublin Society, they would be arranged in the cabinet of Irish insects in that collection, and thus in time material for a catalogue of Irish insects be obtained. Mr. A. Andrews took the chair, while Mr. W. Andrews read a paper on the Crustacea of the West Coast of Ireland. While it was his intention at an early meeting of the next session of the Society to give a complete list of all the Crustacea met with by him on this part of Ireland, including the minute forms, he wished for the present to mention the occurrence there of three species of *Nehalia*, of *Pagurus lævis*, *P. ulidianus*, the latter with ova, of *Pilumnus hirtellus*, *Portunus longipes*, this latter quite new to Ireland, and met with at the entrance to Dingle Bay in fifty fathoms of water, and on a shingly bottom, and of a species of *Galathea* which he regarded rather as a *Munida*. He had taken an immense number of rare minute Crustacea, also many Echinoderms, such as *Echinocyamus pusillus* living, *Spatangus purpureus*, *Ophiura alba*, and young *Echinus lividus*, or at least something very like it, at fifty fathoms depth. Further notices of all these species he would reserve for another occasion. Professor Macalister remarked on the interest of the paper, and said that from the sample of it given now, the paper promised for next session will be of great value, many of the species alluded to being rare. Professor Macalister exhibited a specimen of *Ommastrephes* from the Cape of Good Hope, which if not one of Le Sueur's species, was probably undescribed. A vote of thanks was then passed to the Royal Irish Academy for so kindly accommodating the Society with the use of their house during the past session, after which the chairman adjourned the Society until the first Wednesday in November next.

Royal Geological and Royal Zoological Societies, June 8.—John Barker, M.D., in the chair. The Rev. M. H. Close read a paper "On some Corries and their Rock-basins in Kerry;" the object of which was to demonstrate, if possible, what is still denied by some, the considerable erosive power of a corry glacier. On account of its smallness (its mean diameter being only 550 ft.) the well displayed basin in massive unfaulted rock, in the mountain hollow called Coom Keagh, a well-known glacier site near Dingle, peremptorily disclaims all the explanations hitherto suggested for such physical features, save that of glacial action. The water in the basin is 42 ft. deep, and the mean height of the rock-barrier above the water is 10 ft. The glacier must have removed at least 52 ft. of rock from the site of the basin, and doubtless more, since the rock basin is due only to the difference between the erosion at its middle part and at the rock barrier. The Rev. Professor Haughton and Professor Hull took part in the discussion on this important paper.—Professor R. H. Traquair, M.D., read a paper "On the scales of *Calamoichthys calabaricus*." He described the external hard parts of this fish, including the scales, fin-rays, and those cranial bones which have external "ganoid" surfaces, in this supplementing as well as somewhat correcting the description of Dr. Smith. Especial attention was given to the scales; their whole surface is covered with closely-set punctures, rather irregularly placed towards the centre and anterior superior angle, but assuming a regular arrangement in concentric and also radiating lines on the posterior inferior part of the scale. The microscopical structure of the scale corresponds with what is seen in *Polypterus*. The scales are of an osseous substance, with numerous lacunæ. Vascular canals enter from the attached surface, and then form a complex network which communicates by minute branches with the punctures in the external aspect. The form of the scales on different parts of the body was also alluded to, and some deviations observable on some specimens from the usual regular arrangement of the scales in oblique bands were also described.—Professor Macalister, M.D., then read some letters addressed to the late Dr. Croker respecting a singular mode of reproduction of the Marsupials. The writers were Mr. Williams, M.R.C.S., and Mr. G. T. Lloyd, of Geelong; and after asserting that all the knowledge at present existing on the subject of the reproduction of the kangaroo was erroneous, proclaimed as an important discovery that the young kangaroo was developed from a little mass of mucus which exuded at certain seasons from the nipple of the mother. The Chairman, in calling for a discussion on this correspondence, stated that the actual transit of the young animal from the uterine cavity to the maternal pouch had never yet been proved. [We cannot refrain from expressing our regret that the members of two learned societies could be found to listen to such absolute nonsense as was contained in these letters, and that a professor of zoology in an ancient university, himself a distinguished anatomist, could be persuaded to be the medium of presenting it to such or any audience. As to the remarks of the Chairman, who we think ought to have stopped the reading of the letters, need we say that they are in contradiction to the facts observed by the late Earl Derby's father, or by the present Professor Owen.]—Professor R. Ball read an interesting letter from a friend in Bristol referring to the birth in the Zoological Gardens of that city of a second litter of four tiger cubs. Of the first litter of four, only one survived; and of the present litter all the cubs were more or less malformed and delicate. In Dublin the tigress has never had any offspring, while the lionesses have been most prolific, and their cubs are uniformly perfect and healthy. The societies then adjourned to the next session.

Royal Dublin Society, May 23.—Prof. Dyer in the chair. Prof. R. Ball, M.A., read "An Account of Experiments on the Mechanical Efficiency of the Differential Pulley-block and Epicycloidal Pulley-block."—Dr. T. Emerson Reynolds read a paper "On a Series of Mineralogical Tables."

Royal Irish Academy, May 23.—The Rev. J. H. Jellett, B.D., president, in the chair. Dr. R. M'Donnell read a paper "On a New Theory of Nervous Action, as regards the Propagation of Sensation along Nerves." This memoir will be published in the Transactions of the Academy.—A paper by Mr. Hardinge was read, "On an ancient seal of the diocese of Ossory, and on some coins found near the Boyne."—The following were declared duly elected members of the Academy:—A. FitzGibbon, C.E., E. Hutchins, and John Kelly, of University College, Calcutta.

BERLIN

Royal Prussian Academy of Sciences, March 14.—Prof. Dove read a communication on the diffusion of heat in the Polar Sea, and on the cold of the early part of the present year, the latter accompanied by tables.

March 31.—Prof. Helmholtz communicated a memoir by M. N. Baxt on the velocity of transmission of excitation in the motor nerves of man, containing the results of several series of experiments.—Prof. Hofmann read a paper on substituted melamines, in which he described the following compounds—trimethylmelamine, triamylmelamine, and triphenylmelamine. He confirmed his previous supposition that the substituted melamines are not the direct products of the desulphuration of the sulphur-compounds of urea, but that this formation is preceded by that of the substituted cyanamides. Prof. Hofmann also communicated a memoir by himself and M. Otto Olshausen on the isomers of cyamuric ether, in which the authors describe the cyanætholine of Cloëz, and a series of experiments on the production of the cyanuric ethers of the methylic, ethylic, amylic, and phenylic series.—Prof. W. Peters read a paper on the affinity of the *Ctenodactyli* to the chinchillas and other groups of rodents, in which he stated that the African genera *Ctenodactylus* and *Pectinator* differ in all essential points from the jerboas (*Dipus*), and agree rather with *Chinchilla*, and *Octodon*, or *Echinomys*, whilst they show some tendency towards the *Murinæ*.

April 7.—Prof. Rammelsberg read a paper on the position of thallium in the series of elementary bodies. He described several salts of thallium, such as the iodates and periodates, the chlorides, bromides and iodides of thallium and their double salts, and referred to the isomorphism of the salts of thallium with those of potassium (rubidium and ammonium) as shown especially by the researches of Des Cloiseaux. He stated that although both physically and chemically thallium is a metal, it presents a combination of characters in its compounds which renders its precise location difficult. Prof. Poggendorff noticed a new form of electrical machine, upon which he promised full details at a future meeting of the Academy.

April 28.—A memoir by Dr. P. Groth on the relation between crystalline form and chemical constitution in some organic compounds, was communicated by Prof. G. Rose. The author remarked upon the failure hitherto experienced in all attempts to apply the theory of isomorphism to organic compounds, and stated that he adopted a new method of investigation, which consisted in ascertaining the nature of the change produced in a given crystalline form by the access of a definite atom or atomic group replacing hydrogen. He described a long series of experiments, which lead him to conclude that there are atoms and atomic groups, which, by substitution, alter the crystalline form of a body only in a certain direction. This change he proposes to call "morphotropism," and he indicates the different modes in which the "morphotropic force" may be modified in action.

German Chemical Society, June 13.—Prof. Hofmann has employed his method for taking vapour-densities, to control the formulæ of several organic compounds. Sulphuretted methylic aldehyde (or what has been considered as such) is $C_3 H_6 S_3$. The vapour-density taken in xylidine-vapour was found to be 70·72° instead of 69° required by the theory. The corresponding ethyl compound was found to be $C_6 H_{12} S_3$. It is more volatile than the methylic compound. Chinone (prepared from benzidine instead of aniline, the former giving a better result) has the formula $C_6 H_4 O_2$, and not the double formula which has been lately proposed for it. He then showed a fine specimen of anthrachinone prepared by Messrs. Hopkins and Williams of London.—M. Schlebusch has prepared some derivatives of camphoric acid, and of camphor, notably tetranitro-camphor.—W. Thomsen, who has lately published views on the connection of the basicity of an acid, and the heat developed by its combination with water, draws conclusions from this theory as to the basicity of silicic, hydrofluoric, and fluosilicic acids.—L. Henry described chloroiodides of ethylene, and of allyl.—A. Kekulé described the properties of crotonic acid prepared from aldehyde, from oil of mustard, and from cyanide of allyl; the latter two being identical. The former melts at 72°, boils at 184°·7 C., and crystallises in the monoclinoëdric system.—M. Daube has extracted the colouring principle of the curcuma-root. He gives to it the formula $C_{10} H_{10} O_3$, and the name curcumin.—W. Knop has published a preliminary notice of the action of sulphuric acid and alcohol on albumen.

GÖTTINGEN

Royal Society of Sciences, January 5.—A paper, by M. Max Nöther, on Algebraical Surfaces which may be represented by plane figures, was communicated by M. A. Clebsch.

January 19.—MM. W. Marmé and A. Creite communicated a paper on the Physiological Action of the Alcoholic Extract of *Cynoglossum officinale*. The authors deny that this extract acts in the manner of curare, as stated by some Russian writers; they describe its action as that of a narcotic, and state that it causes death by paralysing the respiratory centre. Dr. Rudolph Fittig communicated some further researches upon the constitution of piperic acid, in which he described several of its derivatives. Professor Wöhler noticed the analysis of the supposed meteoric iron of the Collina di Brianza, by Dr. Haushofer, who had stated that he found in it both nickel and cobalt, the presence of which was denied by previous analysts. The author had analysed a portion of this iron, and had also applied to Professor Rose for an analysis of the fragments in Berlin; no trace of cobalt or nickel was detected by them. Dr. Haushofer's analysis was probably made from a fragment of true meteoric iron.

February 16.—M. Clebsch communicated a memoir, by M. S. Lie, on the relations of reciprocity of Reye's complex. Dr. Rudolph Fittig read a paper on Tetramethylbenzole, in which he described a new solid hydrocarbon, having the formula ascribed to tetramethylbenzole $[C_{10} H_{14} = C_6 H_2 (C H_3)_4]$. For this he proposed the name of *durole*, and he described two of its compounds, namely, *dinitrodurole* and *dibromodurole*.—Professor A. Enneper read a paper on an enlargement of the idea of parallel surfaces.

March 16.—Professor Kohlrausch communicated a memoir, by M. E. Riecke, on the replacement of a system of galvanic currents existing upon a surface by a distribution of magnetic masses.—Professor Henle communicated some zoological observations made at Naples by Dr. Alexander Stuart, of Odessa. The author described the development of new individuals in a colony of *Collozoum inerme*, which takes place by a process of gemmation. He confirmed his former statement that the cilia of *Coscinosphæra* are composed of calcareous crystals. With regard to the medusa-brood of *Velella spirans*, the author stated that all the tissues of the polypary take part in their formation, and that at an early period they possess a body cavity distinct from that of the stomach, which is afterwards filled up with connective tissue, so as to leave only the canals of the water-vascular system. He noticed the occurrence of something which he regards as a digestive passage in the *Gregarinæ* of the earthworms, and briefly described the nervous system of *Creseis acicula*, in which he found a ganglionic œsophageal ring and dorsal and ventral ganglia, each of the latter emitting nervous stems.

DIARY

THURSDAY, June 23.

Zoological Society, at 8.30.—On the Walrus: Dr. J. Murie.—Catalogue of the Mammals of South China and Formosa: Mr. R. Swinhoe.—On a Collection of Birds from the Island of Trinidad: Dr. O. Finsch.

SUNDAY, June 26.

Sunday Lecture Society, at 8.—Cruelty in relation to the Lower Animals: Dr. T. S. Cobbold, F.R.S.

MONDAY, June 27.

Ethnological Society (Extra Meeting), at 8.—On the opening of the Park Cwm Tumulus: Sir John Lubbock, Bart.—On the opening of Grim's Graves, Norfolk: Rev. Canon Greenwell.—On the discovery of Platycnemic Men in Denbighshire: W. B. Dawkins and Prof. Busk.

London Institution, at 4.—Botany: Prof. Bentley, F.R.S.

WEDNESDAY, June 22.

Society of Arts, at 4.—Anniversary Meeting.

BOOKS RECEIVED

English.—Woolhope Naturalists' Field Club: Report for 1869.—Remarks on Synonyms of European Spiders, No. 1: T. Thorell (Williams and Norgate.)

Foreign.—(Through Williams and Norgate).—Bericht über die Fortschritte der Anatomie und Physiologie im Jahre 1869: Henle, Meissner und Grenacher.—Die Ophthalmologische Physik und ihre Anwendung auf die Praxis: Dr. H. Gerold.—Nouveaux éléments de Physique Médicale: Desplats et Gabriel.—Die Bierbrauerei und die Dickmaischbrauerei: P. Heiss.—Etude sur les Diatomacées: Ch. Manoury.—Die Land und Süsswasser Conchylien der Vorwelt: Dr. Sandberger.

NATURAL SCIENCE AT THE ROYAL ACADEMY

I AM afraid the words of the title of this article will sound like a harsh discord to many ears. Let not the reader suspect that they are in any way akin to that incongruous phrase "art manufacture."

I do not presume to address persons versed in the language of the artistic schools, nor the vaguely vapouring sentimentalists who are leaders of æsthetic cliques.

I know a class of men more worthy of respect who are happily more ignorant: men who are accustomed to attach a defined significance to words: men who, when they hear noises that they do not understand, or when they detect the characteristic haziness of artistic cant, stand meekly on one side, careful and troubled only to pursue the orderly and laborious track of mere matters of fact. It is remarkable that the chasm which separates those groups of men who work in the adjacent fields of art and science is one of the most distinct in the whole system of modern life; as marked as that which divides the official from the commercial mind, for instance, or the sacerdotal from the legal caste. There is no common ground between them. They do not teach their young in the same language; the scientific men generally talking in grammatical and reasonable speech, whilst those who speak on behalf of art generally "gas," if I may be allowed to use an expressive americanism.

A small section of the crowd who throng the Academy galleries at this time of year, persons who habitually associate reason with observation, have been known to complain that the exertions of the painters are to a great extent wasted upon them for want of rudimentary knowledge of the principles upon which fine art is founded, and that the information which probably exists somewhere upon this subject seems to be so mingled with rhetorical flourishes and anecdotes, that if not altogether inaccessible, it demands far more time than most students can afford, to sift it out, so that when they go to look at pictures, they do so in the idlest possible temper, expecting to be merely amused with a pleasant but transient sensation like the smelling of a sweet odour, yet all the while not without misgivings that they might be deriving nobler entertainment or more permanent good. Are pictures mere accidents, or are they produced upon known principles? Are their excellencies estimable by definite methods and referable to known standards, or is it all caprice?

Such questions are very pertinent, and ought to be philosophically answered by able painters, but it happens that such men have not generally cared to spend their energies in speech. If a living painter offers one or two hints concerning the Academy, such as can be written in a weekly journal, they must needs be of a general kind, and with little, if any, reference to particular pictures. In any case, if they do not harmonise with the prevailing tone of dilettantism, they will stand as landmarks of heresy to be kicked against by critics. In the columns of NATURE, however, they will only be read—if at all—by clear-headed and simple-souled naturalists.

The central motive of fine art may be most compactly expressed by the simple term beauty. We will not stop to define the word now. Go to the Academy to seek for it. Do not expect much of it; for amongst the four or five hundred essayists on canvas there represented, a good many, perhaps more than half of them, would repudiate that fundamental principle. Be content to take your beauty in small doses: about in the same proportion as pure gold to the pebbles in the bed of an African river, or sense in a railway novel. When found, enjoy freely in your own way. That is the first stage in artistic culture; some people say the whole—beginning, middle, and end of it. But this will hardly satisfy the scientific student. He will want to find out the relation between beauty and the common world, so as to determine what position this exquisite sensation ought to occupy in the order of his experiences.

Let him then proceed to examine the pictures analytically, and, by way of making a beginning, let him apply a test question all round. Let him ask himself, for instance, whether any example of beauty has been offered to him which depends on a violation of natural laws; whether he has come across anything like a lovely monster. The question may appear to be an idle one, but there is a principle involved in it of the very highest importance, though there is no time to illustrate it here. Let him think it over carefully, and apply it not merely to pictures of monstrous animals and vegetables, but to any abnormal effect of the sun's rays, any deviation from the simple laws by which surfaces govern shadows, and so on; any monstrous clouds, apparently constructed out of featherbeds, and yet beautiful; any monstrous draperies, apparently made of bent metal, or cut in horn, or forced into novel shapes as if by explosive gases, and yet beautiful; any monstrous contortions of the human countenance amongst the large variety of attempts to represent the pleasanter, or more repulsive, or more permanently interesting phases of human life. Let him take note whether he is likely to carry with him to his grave one image or suggestion of loveliness that will have had its origin in a picture produced in ignorance of or defiance of natural law; because, if he find any, the fact will be well worth knowing, and I hope he will not hush it up.

Another hint that I will venture to give the scientific student is, to remember that in these days art, in England, is in its infancy. By the time that the play-going public have sickened themselves with displays of trivial sentimental incident; by the time the new-born professors of art at the universities have taught all the growing boys how life may be treated artistically after it has been earned by doing their day's grinding at the mill; by the time these boys have travelled and studied the art of the ancient world and its relation to the modern; by that time there will have become established a school of original painters, able to represent with ease and accuracy any visible fact, and free to choose out from the procession of physical phenomena such special incidents or moments of visible history, such elements of passing scenes as shall be most profoundly beautiful and delightful to men, and to preserve in comparative permanence their evanescent charms.

I took up a scientific periodical the other day, and lighted upon a letter to the editor concerning the colour of the sky, written of course by a scientific man (one who seems to have read that silly little book by Chevreul on complementary colours), in which he suggests that as the sun looks orange, *therefore* the sky looks blue. He says that upon this theory the planets of Sirius and Vega must have a black sky, those of Betelgeuse a green sky, and so on. But if my readers go to the Royal Academy, some of them will probably be a little surprised to find that they are positively living on a planet which enjoys the advantage of a solid lemon-yellow sky! a sort of information not to be picked up every day. In the same sort of way, ethnological students may inform themselves that the ancient Greek heroines were shaded with streaks of treacle about their "great marbly limbs." But the judicious investigator will take note that the chief end of most of this canvas, and the purpose of most of this paint, is to indulge the artists and their disciples with reminiscences of antecedent art—an exemplification of the cud-chewing tendencies of his species. Many of them have drank deeply at the fountain of second-hand beauty; they have drank perhaps intemperately, and their speech must needs be somewhat sublime to uninstructed ears.

Let not the student carry away the impression that artistic faculties and wanton inaccuracy are necessarily connected. If the scientific writer who offered suggestions to account for the blueness of the sky had acquired the habit, which the practice of painting gives, of comparing the intervals between different colours, and estimating the intensities as well as the extent of the several elements that go to make up any given scene in the out-of-doors world, he could hardly fail to notice that the sun at mid-day would in all cases be the least coloured object in the whole field of view; that the colours of other objects would neither gain nor lose perceptibly where exposed to his direct rays; whereas, the shaded and overshadowed parts of them would suffer various enhancements or modifications from the coloured rays reflected from surrounding surfaces; and that, in the case referred to, in a mid-day cloudless sky, the most widely extended and most purely coloured of all the surrounding spaces being blue, all the shadows and many of the shades would be dyed blue, so to speak, over their own proper colours; and that the whole scene would be steeped in the "blue flood of light" of the poets. The colours of the face of our planet, both native and derived, present a large field for study, and a good deal more can probably be ascertained about them than about many less pleasant yet less neglected subjects; and when the scientific investigators have done with the blue sky, I hope they will let us hear what they have to say of the blue sea.

What is the moral of all this? Simply that the scientific men pay too little attention to the broader aspects of the visible world; while the artists on their part pass by the clear fountain of natural beauty, and content themselves with dreamily sipping lukewarm water from the corroded vessels of their forefathers; the one group of doers standing apart from the other; whereas, if either would go to school with the other, they would, in my opinion, each stimulate and aid the labours of the other, and divide between them a far larger share of the spoils of the world.

JOHN BRETT

ON THE NATURAL LAWS OF MUSCULAR EXERTION

AMONG a multitude of profound and happy suggestions to be found in Mr. Babbage's Economy of Manufactures, are some remarks on the relation between fatigue and the rapidity or degree of muscular exertion. Coulomb, it appears, had previously investigated the most favourable load for a porter, and had ascertained by experiment that a man walking upstairs without any load, and raising his burden by means of his own weight in descending, could do as much work in one day as four men employed in the ordinary way with the most favourable load. Mr. Babbage clearly points out (p. 30) that the exertion necessary to accomplish any kind of work consists partly of that necessary to move a limb of the body, and partly of the force actually utilised in the work. The heavier the work done, the larger the proportion, therefore, of the power utilised. But there is a limit to this mode of increasing the useful effect, because, by the natural constitution of the muscles, they can only develop a limited amount of force in a given time, and the fatigue rapidly increases with the intensity and rapidity of exertion. Hence there is in every kind of work a point of maximum efficiency, which is in practice ascertained more or less exactly by frequent trial.

This subject appeared to me to possess interest for at least two reasons: it might be made to throw some light upon the chemical and physiological conditions of muscular force; it might also point out how we could make some commencement, however humble, of defining the mathematical relations upon which the science of economy is founded. I have therefore attempted to add precision and certainty to the ideas put forth by Coulomb and Babbage, by some experiments of a simple kind.

The first and least interesting series of experiments consisted in ascertaining the comparative distances to which various weights could be thrown upon level ground. The product of the weight and distance was taken as the measure of useful work, and it was the object to ascertain according to what law this varied, and at what point it was a maximum. The weights employed varied from ½ lb. up to 56 lbs., and were thrown as nearly as possible in a uniform manner and at the most advantageous angle. About 57 experiments at different times were made with each weight, or 456 experiments in all; and it was quite obvious that good average results were obtained, the correspondence of different sets being very satisfactory. The results are as below:—

Weight in pounds	56	28	14	7	4	2	1	½
Average distance thrown in feet.	1·84	3·70	6·86	10·56	14·61	18·65	23·05	27·15

A little consideration showed it to be probable that these numbers would agree with an equation of the form—

$$x = \frac{p}{w + q}$$

in which x = distance thrown,
w = weight thrown,
q = constant weight representing about half that of the arm,
p = constant amount of force exerted.

The experiments give us eight distinct equations by which to determine the two unknown quantities p and q; and by the method of least squares we determine their most probable values to be—

$$p = 115{\cdot}7$$
$$q = 3{\cdot}9$$

The formula thus becomes—

$$x = \frac{115{\cdot}7}{w + 3{\cdot}9}$$

And calculating thence the distances for the several weights, they are:—

Weights ...	56	28	14	7	4	2	1	½
Calculated distances	1·93	3·63	6·46	10·61	14·65	19·61	23·61	26·30
Differences from experiment	+·09	−·07	−·40	+·05	+·04	+·96	+·56	−·85

The correspondence is so close as to show that the formula is in all probability the true one, and the quantity 3·9 does not differ much from half the weight of the arm, which might be expected to enter into the question. The fact is that the correspondence is embarrassingly close, and I am inclined to attribute it partly to chance. The experiments could hardly have been expected to give results accurate to an inch or two in some cases, and though the formula must be considered true on the ground of experiment, I do not quite see how to explain it on mechanical principles.

If we regard the useful effect as the moving of the greatest amount of matter, it is $x \times w$, and, theoretically speaking, increases continually with w. For the different weights and calculated distances, it is as follows:—

Weight...	56	28	14	7	4	2	1	½
Useful effect	108·1	101·6	90·4	74·3	58·6	39·2	23·6	13·2

But in reality it was not possible to raise the larger weights without exerting additional force unconsidered in the formula, so that the practical maximum of efficiency is probably about 28lb., in the case of my own right arm. With different people it would, of course, vary somewhat.

The above experiments completely confirmed Mr. Babbage's remarks, but did not seem to lead to any further results. I proceeded, therefore, to other experiments upon the rate of exhaustion of muscular fibre. One mode of trial was to raise and lower various weights by a pulley and cord through the convenient range of the arm, continuing the motion with unrelaxed rapidity until the power of the muscles was entirely exhausted. The results of more than fifty experiments were as follows:—

Weight lifted ...	56	42	28	21	14
Average number of times	5·7	11·9	23·0	37·6	111·0
Useful effect ...	319	500	644	790	1554

These numbers show that the total greatest amount of labour can be done with small rather than large weights in this case; but they fail to give any regular law, owing probably to the weight of the body being brought into use with the larger weights.

The mode ultimately adopted was to hold out various weights in the hand at the full stretch of the arm, and to observe the times during which they could be supported. No two experiments were made with the same arm, without allowing, at least, one hour to elapse, so that the vigour of the muscles might be restored. With the smaller weights there was naturally some uncertainty as to the time, but in the case of the large ones the time was very definite. Altogether 238 experiments were made, an equal number with each arm. Uniting all the experiments for the same weight, the results are:—

Weight ...	18	14	10	7	4	2	1
Times in seconds	14·8	32·5	60·3	87·4	147·9	218·9	321·2

These results are pretty satisfactory averages; thus the probable error, for two cases indifferently chosen, was, for 18lbs. in the left hand about ·5, and for 4lbs. in the right 2·7, and the error of the combined results would be less. With the exception of the results for 10lbs. in the left arm, which appear to be somewhat in excess, these numbers are very regular, and point to a systematic law governing the rate of fatigue. The useful effect, or the product of the weight and time, shows a decided maximum, about 7lbs., as follows:—

Weight	18	14	10	7	4	2	1
Useful effect	266	455	603	612	592	438	321

If the weight held be very small, much power is lost in merely sustaining the arm; if the weight is large, there is comparatively little loss on that account, but the power of the muscles is soon run out, and no sufficient opportunity for restoration is allowed. The weights chosen for dumb-bells and other gymnastic exercises appear to be about those which give the maximum efficiency.

I have made several attempts to explain these numbers by reasonable suppositions as to the conditions of exhaustion and restoration of muscular power. It seemed reasonable to suppose that the supply of new matter from the blood would increase in some proportion to the vacancy or want of it, but all such conditions led to integrals of a logarithmic form, which could not be easily compared with experimental results. No formula that I obtained could be made to agree properly with the figures, and all that can be said is that the curve representing the results has a certain appearance of a logarithmic character, so far agreeing with the formulas obtained. Those who are acquainted with the physiology of the subject might succeed better; I am not sure, for instance, how far the failure of strength is due to the exhaustion of the original substance of the muscle, how far to the inadequacy of the current supply of blood. It is a question again how far in any case of muscular action the supply is promoted by the increased action of the heart, or checked by the possible constriction of the arteries. If these questions have not been or cannot be otherwise decided, they might, perhaps, be indirectly solved by experiments of the kind described.

My own object, however, was not to intrude into the domain of physiology, but to show that definiteness might possibly be given by degrees to some of the principles and laws which form the basis of the science of political economy. In some speculations upon the mathematical theory which must underlie that science (read at the British Association in 1862, and published in the Journal of the Statistical Society for June 1866, p. 282), I endeavoured to show that it was only the excessive difficulty of determining the character of the functions involved, which prevented economy from taking the mathematical form and standing proper to it. There is little doubt as to the principles of the subject; but when we try to put them into figures, the data are found to be so deficient, complicated, variable, and subject to disturbances of all kinds, that any hope of accuracy soon dies away in most cases. In the above experiments I have attempted to determine the exact character of the functions connecting the amount of work done with the intensity and duration of labour in certain simple cases. These cases, however unimportant in themselves, represent principles which have innumerable applications in common life.

W. STANLEY JEVONS

THE NEW ZEALAND INSTITUTE

Transactions and Proceedings of the New Zealand Institute, 1868. Vol 1. Edited and published under the authority of the Board of Governors of the Institute, by James Hector, M.D., F.R.S., Wellington. (London: Trübner and Co.)

OUR brother philosophers at the Antipodes have set us an example that we should do well to follow in this country; those who reside at head-quarters (Wellington) and who form the New Zealand Institute, having affiliated to themselves under a special Act of the Legislative Government, the various other societies engaged in similar pursuits that exist in the New Zealand Islands; and who in consequence transmit their papers, or abstracts of them, to the Institute for incorporation in their Transactions. It is to such an organisation as this that we must look for relief from the overwhelming pressure of miscellaneous scientific literature under which the British naturalist now groans. No matter what branch of science he affects, or in how narrow a groove of it he walks, the number of Transactions, Proceedings, Journals, &c., with which he must keep *au courant*, is the great obstacle to his progress; and if he at all takes a broad view of his science, he must be content that it should be a superficial one, and increasingly so as new societies and journals spring into being.

The rules and statutes of the New Zealand Institute appear to be under parliamentary control, and have little analogy with the charters of our free-born societies:—they were published in the *New Zealand Gazette* of March 9, 1868, and the following is a summary of them:—

Art. 1. Any society desirous of incorporation must consist of twenty-five or more members, and subscribe 50*l.* annually for the promotion of the branch of knowledge it professes.

Art. 2. Incorporation ceases on the failure of these conditions.

Art. 3. Any such society must expend either one-third of its annual revenues in or towards the support of a local library or museum, or one-sixth of its revenues to the extension and maintenance of the museum and library of the Institute.

Art. 4. Failure of this condition is followed by cessation of incorporation.

Art. 5. All papers read at such societies shall be regarded as communications to the Institute, and be published by it, under the following regulations:—

(*a*) The publication shall consist of a current abstract of the proceedings of the incorporated societies, and of papers read before them; and shall be entitled "Transactions of the New Zealand Institute."

(*b*) The Institute has the power to reject papers, but (*c*) must return them. (*d*) A proportional contribution for the cost of publishing the Transactions may be demanded of the societies in respect of the papers they contribute; and (*e*) a proportional number of copies of the Transactions will be sent to each society; which may also (*f*) have as many copies as it pleases, at cost price.

Art. 6. Funds and properties derived from the societies shall be vested in the Institute, and applied by its governors to public uses.

Art. 7. The incorporated societies shall conduct their own affairs, making their own bye-laws, &c.

Art. 8. Certificates of incorporation are granted upon application and compliance with the foregoing conditions, under the seal of the Institute.

The museum and library of the Institute are under the management of the Board of Governors; the laboratory is under the exclusive management of the manager of the Institute.

The governors are nine in number: the official ones are the Governor of the Colony, the Colonial Secretary, and the Superintendent of Wellington; joined to six men, eminent for their scientific attainments or love of science; amongst whom are Dr. Hector, who is likewise manager, and the Hon. Col. Haultain, who is likewise hon. secretary and treasurer. There are four affiliated societies: the Wellington Philosophical Society, the Auckland Institute, the Philosophical Institute of Canterbury, and the Westland Naturalists' and Acclimatisation Society.

With regard to the contents of this first volume, it opens with a capital purpose-like address from the Governor, Sir. G. Bowen, which is followed by a series of papers, for the most part of very great scientific value and interest, and which give a very favourable idea indeed of the spread of scientific knowledge in the Colony, and the number of earnest workers it contains.

Of these, those comprising the Transactions contain no fewer than twenty-two articles on Geology, Physics, Botany, Ornithology, Applied Sciences, Wave and Earthquake phenomena, &c.; these are followed by thirty-nine papers and verbal descriptions of scientific phenomena; and these again by ten essays of great research and merit, respectively entitled:—

"On the Geographical Botany of New Zealand," "On the Leading Features of the Geographical Botany of the Provinces of Nelson and Marlborough," "Remarks on a Comparison of the General Features of the Flora of the Provinces of Nelson and Marlborough, with that of Canterbury," "Sketch of the Botany of Otago," "On the Ornithology of New Zealand," "On the Botany, Geographic and Economic, of the North Island of New Zealand," "On the Cultivation and Acclimatisation of Trees and Plants," "On the Geology of the North Island of New Zealand," "Short sketch of the Maori Races," "On the Maori Races."

The last of these is the result of the life-long labours of one of the most accomplished and industrious of the early missionary settlers in the North Island, Mr. Colenso; whose botanical researches have been as important as his ethnological labours. The typography of the work is very good, but the illustrations are unequal, and often much larger than they need be for all they demonstrate.

From such an excellent beginning who can doubt that important results will quickly follow? To us the experiment of affiliation is a very interesting one, the success of which we hope to witness. That there are in the New Zealand scheme sources of failure is obvious, but we see none which may not be overcome by firmness, judgment, and singleness of purpose, on the part of the head Institute, and by the avoidance of petty jealousies, and a due regard to the interests of Science on that of the affiliated societies. The power vested in the governors of rejecting unfit papers is a most valuable one, if conscientiously exercised; it cannot be too vigilantly watched by the contributors to the Institute, nor too carefully conducted by the governors. In this country the power vested in the councils of our societies, of suppressing papers on the advice of competent referees, works on the whole well, though we could indicate societies, and some of high position, too, which have quite recently published in their Transactions worthless matter, that has evidently never been examined by a council, nor reported on by competent advisers; thus squandering the property of the members, and doing discredit to the science which the members represent.

Is it too much to expect that our powerful and comparatively wealthy societies should affiliate some of their weaker brethren, who devote themselves to the same branches of science? applying their own tests to the admission of contributions to their Transactions, and leaving to lesser societies the freedom to govern themselves as they think best. Of such an affiliation many of the lesser societies would be proud, and the greater could not but benefit by the arrangement.

To one other point only we shall allude in reference to the Transactions of the New Zealand Institute, viz., the advisability of breaking it up, now or at some future time, into series treating of certain branches of science, for the convenience both of workers and purchasers. By so doing, the members would set another example well worth following by some of the oldest, gravest, and most learned of the English, Irish, and Scotch scientific bodies, which publish ponderous quartos of mixed sciences, that are worth neither their shelf-room nor their cost of binding to the mass of the members and purchasers. But we shudder at the thought of suggesting to such august bodies as the Royal Societies of London and Edinburgh, or the Linnean Society, or the Royal Irish Academy, the propriety of breaking up their Transactions into series confined to definite branches of science, and husbanding their funds by giving to their members and correspondents such only as they care to have.

OTHER WORLDS THAN OURS

Other Worlds than Ours. By R. A. Proctor. (Longmans, 1870.)

THAT Mr. Proctor could write, if he were so disposed, an excellent and instructive book on certain branches of Modern Astronomy, we have no manner of doubt; but for the successful accomplishment of such a work, it would be necessary, in the first instance, to settle in his own mind what particular classes of persons the work was intended to suit; and, in the second place, it would be essential for the author to allow himself sufficient time for the completion of his project. It is from a failure in these two particulars that what would otherwise have been a truly remarkable book, is brought down to a level much below Mr. Proctor's actual abilities.

A large portion of the book is devoted to the not very fruitful question of the habitability of the planets or their satellites by beings not generically very different from the human race; but we do not think the question in Mr. Proctor's hands is advanced on either side of the argument, materially beyond where Whewell and Brewster left it. The chief novelty consists in the hypothesis that Jupiter and Saturn may possibly serve as suns to at least some of their satellites; and, by the partial emission of heat (and light?), may compensate for the extreme remoteness of the central orb of the solar system. We can neither follow nor admit the validity or consistency of Mr. Proctor's arguments. The question whether the larger planets have or have not as yet cooled down, by radiation, to a sort of normal temperature, is one of considerable interest, and lies within the scope of astronomical physics; but we cannot say that Mr. Proctor's remarks either remove or elucidate the difficulties of the points at issue. On the contrary he speaks fitfully, and hesitates between doubt and something bordering on dogmatism. For instance, in page 140, he writes thus: "We seem led to the conclusion that Jupiter is still a glowing mass. . . ." Two pages onward he remarks: "He (Jupiter) is not an incandescent body;" and then after he has given his own opinion, that Jupiter is still . . . . "fluid probably throughout, and seething with the intensity of primæval fires, ..." he forthwith falls foul of the late accomplished Dr. Whewell, in terms such as these: (p. 145) . . . . "Surely no astronomer, worthy of the name, can regard this grand orb as the cinder-centered globe of watery matter, so contemptuously dealt with by one who, be it remembered thankfully, was not an astronomer." Our readers will probably feel that such language is to be regretted, and is alike unworthy of Mr. Proctor, and inapplicable to Dr. Whewell.

We have been induced to select the foregoing passages, because they are in fact typical of the style in which Mr. Proctor's volume is written. Laplace, the elder and the younger Herschel, Humboldt, Admiral Smyth, Sir William Thomson, Mr. Tait, Dr. Balfour Stewart, Professor Tyndall, and other honoured names, all in their turn come under Mr. Proctor's adverse criticism with greater or less severity. Mr. Lockyer is the object of our author's especial censure; simply because his opinions do not square with those of our author on the nature of the solar corona visible during a total eclipse, and on which subject wise astronomers confess their profound ignorance, therefore Mr. Lockyer's opinion is condemned as "erroneous," which it may or may not be, and Mr. Lockyer himself is represented as impeding the progress of science! This strong and repeated reference to what our author regards as the scientific peccadillos of an eminent observer, seems to us all the more unnecessary, from the fact, of which Mr. Proctor must be well aware, that one main purpose of the proposed British expedition to view the forthcoming solar eclipse, is to ascertain, if possible, what is the real nature of the mysterious light which forms the corona, and which often streams from the solar photosphere in extended and fantastic forms. We venture to suggest that, for the promotion of that calmness of spirit which is essential to the successful investigation of scientific truth, the refutation of scientific error should in all cases be free from even the appearance of strife and personality. But, passing from the criticisms on Mr. Lockyer's theory of the solar corona, the fate of Mr. Lassell, the present accomplished and experienced president of the Astronomical Society, is not more fortunate. Mr. Lassell, after years of careful observation with a magnificent instrument, unique of its kind, comes to the conclusion that not more than *four* satellites of Uranus have ever been certainly observed. Mr. Proctor, however, thus writes: "I have very little doubt that Uranus has at least eight satellites." And again, although our author admits that Sir William Thomson seems to have abandoned his theory of the probable supply of the sun's heat and light by a battery of meteors, nevertheless he thus writes: "*I am quite certain* * . . . . that at least an important proportion of the sun's heat is supplied from the meteoric streams which circulate in countless millions around him" p. 205). We may fairly ask whence has Mr. Proctor this *certain* knowledge of *countless millions of meteoric streams* impinging on the sun? And how can he, with reference to the satellites of Uranus, venture to set his *opinion* in antagonism with the results of the protracted observations of so accomplished and experienced an astronomer as Mr. Lassell?

We may call Mr. Proctor's attention to the probable inadvertency of his description of the hydrogen spectrum as *white*, which it is not in any sense; and to his inexact description of Mr. Carrington's remarkable observation of what may have been a solar outburst. Mr. Carrington did not use, and he could not have used, as Mr. Proctor assumes, a dark glass in projecting the solar image on a screen, and consequently the alleged *breaking of this dark glass* by the presumed solar outburst, could have occurred in our author's imagination alone. These mis-statements, however, are easily corrigible in a second edition, presuming they are not typical of much else in the volume itself.

We think so highly of Mr. Proctor's astronomical knowledge and general ability, that we have ventured to point out what strike us as blemishes in a work which contains so much that is suggestive and valuable. Among the portions that are most suggestive are Mr. Proctor's remarks on the distribution and motions of the stars *in streams*; we are far from satisfied that our author has as yet made good his case; but whether his theory be correct or not, the suggestions are valuable, and afford ample scope for the astronomy of the future. Overlooking, however, and forgetting the blemishes, we feel no hesitation in recommending this volume to the perusal of all who are interested in the progress of one of the noblest and most fascinating of the sciences. Some of the plates which illustrate the volume are a decided advance upon all their predecessors of a like kind, and augur well as promises of yet further improvements.

OUR BOOK SHELF

Balfour's Class-book of Botany; being an Introduction to the Study of the Vegetable Kingdom. With upwards of 1,800 illustrations. Third edition. (Edinburgh: A. and C. Black, 1870.)

PROFESSOR BALFOUR'S "Class Book of Botany" is too well and favourably known to botanists, whether teachers or learners, to require any introduction to our readers. It is, as far as we know, the only work which a lecturer can take in his hand as a safe text-book for the whole of such a course as is required to prepare students for our university or medical examinations. Every branch of botany, structural and morphological, physiological, systematic, geographical, and palæontological, is treated in so exhaustive a manner as to leave little to be desired. The illustrations also form, when enlarged, the very best set of diagrams that a lecturer can have. After this, it may seem hypercritical to find any fault with the new edition. We cannot, however, but regret that the opportunity was not taken of rendering the book still more complete by bringing it down to our present state of knowledge. As stated on the title-page, the additions and corrections are entirely confined to the department of organography, and, as far as they go, are valuable. In particular, the treatment of the subjects of carpology, inflorescence, and phyllotaxis, is rendered much more complete. In other departments we have no such additions, and we miss any reference to the recent labours of Hildebrand, Parlatore, and others, following those of Darwin in the department of fertilisation; of King, Strasburger, and many others in the structure of the reproductive organs of Cryptogams, or to the remarkable observations of Prillieux, Rose, and Brongniart on the movements of chlorophyll. In the department of vegetable palæontology in particular, Unger, Schimper, Heer, Ettingshausen, Dawson, and Carruthers have rendered the science of 1854 scarcely recognisable in 1870; and yet we find not a word added, even to the first edition. The fault appears to be that the book was "stereotyped." Scientific works ought never to be stereotyped. The author has evidently been exceedingly cramped in the insertion of new matter, and the correction of errors has been rendered impossible. Thus we find repeated the old account of the mode of fertilisation in *Parnassia*, which has been shown by both English and Continental botanists to be erroneous, and illustrated by a drawing which is quite incorrect. The work is one, however, which is indispensable to the class-room, and should be in the hands of every teacher. A. W. B.

Proceedings of the London Mathematical Society. Vols. I. and II.

THIS Society met for the first time in January, 1865. At that time the only society in London which received mathematical papers was the Royal Society, while the Philosophical Society of Cambridge naturally took its tone from the university examinations, and paid more attention to the proposal and solution of problems than to the working out of new principles. The present society was formed mainly in order that investigations carried on independently over a wide range of subjects might be compared, and that from the comparison there might grow up some new calculus which should bear to the analysis of the present day the same kind of relation that integration bears to Wallis's elaborate investigations of the properties of the centre of gravity. There were other collateral objects of scarcely inferior importance, such as the improvement and extension of the language of mathematics, the simplification of demonstrations of known truths, and the study of the history of mathematics. There is scarcely a branch of pure mathematics in which the society has not advanced the boundaries between the known and the unknown, but the attention of the leading members has been chiefly devoted to the higher curves.

The introduction of a new word or phrase has often marked an epoch in the history of a science; many of the theories systematised by Darwin are to be found in the writings of others before the happy phrase "natural selection" gave them a simple and enduring shape. Of like importance is Mr. Grove's expression, "correlation of forces," and we find in these proceedings several words, the introduction of which appears likely to play an important part in the development of the science.

The word "quantic" for a "rational and integral function" has been for many years in use, but "deficiency" for the number by which the double points of a curve (including cusps) fall short of the maximum $\frac{1}{2}(n-1)(n-2)$, and "unicursal curves" for those curves in which the deficiency = 0, or, in other words, curves in which the co-ordinates (x, y, z) can be expressed as rational and integral functions of a parameter θ, were first used by Prof. Cayley before this society.

The history of mathematics is enriched by an interesting paper by Mr. Merrifield, showing that the Arabs were acquainted with the property of the radical axis.

Prof. Sylvester's proof of Newton's celebrated rule for the discovery of imaginary roots, hitherto undemonstrated, and Prof. DeMorgan's simple proof that every function has a root (which we should be glad to see in a fuller form) are the principal gains in the mere demonstration of known truths. We could wish to see in print the other communications made to the society by Professors Sylvester and DeMorgan, especially those by the former relating to unicursal derivation of successive points on cubic curves, and to residuals.

We heartily congratulate the society on the vitality and enthusiasm evident in every page of its proceedings, and join with them in their hope that they may shortly obtain a tenement of their own worthy of the great, albeit unostentatious, work in which they are engaged.

H. A. N.

Jahrbuch der K.-K. Geologischen Reichsanstalt. Band XIX. Nos. 3 and 4. 1869.

OF this admirable repertory of memoirs on the geology of the Austrian Dominions, the last two numbers for 1869 have lately reached us. This publication contains the cream of the communications made by members of the Imperial Geological Institution, to which the carrying out of the survey of that great and varied tract of country subject to the Austrian sovereign is entrusted; it always includes many papers of great importance to the student of general geology, and the portions now before us present no falling off in this respect. Of strictly geological papers Prof. D. Stur is the principal contributor. He describes the occurrence of brown coal in the district of Budafa, in Hungary; reports at considerable length on the results of the geological survey of the environs of Schmöllnitz and Göllnitz, also in Hungary; and contributes two other papers of more strictly local interest; but the most important of all the geological memoirs is F. von Hauer's notice of the geology of the Western Carpathians, a most interesting district in every respect. Dr. M. Neumayr's contributions to the knowledge of indigenous fossil faunæ contain descriptions of the univalve shells of the freshwater marls of Dalmatia, and of the Congerian strata of Croatia and Western Sclavonia; the species, many of which are new, are well represented on four plates. Five plates are also devoted to the illustration of another palæontological paper, which will probably possess the most interest of all for extra-Austrian geologists—namely, Dr. E. von Mojsisovics's memoir on the Cephalopod-fauna of the Alpine Muschelkalk, some of the species included in which are remarkable for their wide geographical distribution, especially the characteristic species of the zone (*Arcestes* or *Ammonites Studeri*), which ranges to the Himalayas in one direction, and to Spitzbergen in another.

LETTERS TO THE EDITOR

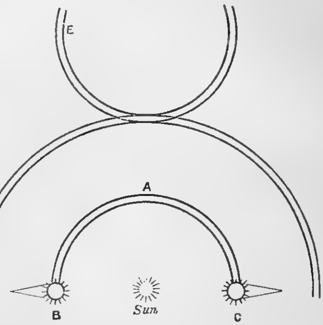
[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Parhelia

(1.) *Seen near Llandudno on 23rd of June, by* JOSEPH PAGET

THIS evening the phenomenon of which a sketch is enclosed was seen here, viz.:—

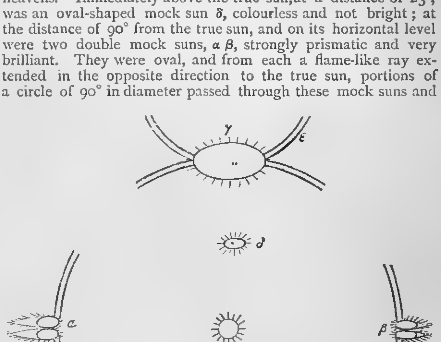
A B C, a portion of a circle of 45° diameter, resting at B and C on mock suns from which a sheaf of light proceeded outwards.



D, a portion of another circle of 90° diameter, at the apex of which was an inverted portion of another circle E of 45° diameter.

(2.) *Seen at Highfield House, near Nottingham, on 23rd of June*

At $7^h\ 36^m$ P.M., there was an extraordinary appearance in the heavens. Immediately above the true sun, at a distance of 23°, was an oval-shaped mock sun δ, colourless and not bright; at the distance of 90° from the true sun, and on its horizontal level were two double mock suns, $\alpha\ \beta$, strongly prismatic and very brilliant. They were oval, and from each a flame-like ray extended in the opposite direction to the true sun, portions of a circle of 90° in diameter passed through these mock suns and



also through an unusually large mock sun γ, situated 45° immediately above the true sun, and which was prismatic and almost too brilliant to look at; from this mock sun there was also a portion of a circle of 45° in diameter.

The phenomenon faded away at $7^h\ 53^m$ P.M. The weather had been hot from the 13th inst., reaching 86·8° in the shade on the 21st, and 86·6° on the 22nd; whilst on the 23rd (the day of this occurrence) it was only 72°, and on the morning of the 24th, the minimum temperature had fallen to 42·9° at four feet, and to 38·2° on the grass, or a fall of 43·8° in temperature in

36 hours. During daylight on the 23rd there was an Aurora Borealis which continued till 1 A.M. of the 24th; at 7 A.M. rain commenced.

Highfield House Observatory, June 24 E. J. LOWE

(3.) *Seen near Burton-on-Trent, June 23.*

The rare and beautiful phenomenon of parhelia was seen by many observers in this neighbourhood at about seven o'clock on the evening of the 23rd inst., and it continued to be visible for more than a quarter of an hour.

The horizontal bar of light, the coloured halo, and the intensified light at the intersections, as also a portion of the upper bow, were all seen very distinctly. The temperature of the atmosphere at the time was rapidly lowering, and during the night a considerable quantity of rain fell.

I presume that the phenomenon was very local, as I have seen no notice of its occurrence in any of the daily papers to which I have had access.

Burton-on-Trent, June 25 EDWIN BROWN

Natural History of Celebes

It will be, perhaps, not without interest to the readers of your periodical to receive the information that I am leaving for Celebes, on a natural history expedition, at the beginning of July, to stay there for a considerable time with the purpose of exploring first this interesting and little known island as far as possible, and this done, the islands in the neighbourhood.

I shall be happy to learn the wishes and supply the desiderata of any naturalist who takes a special interest in the fauna or flora of the island. Letters will reach me Poste Restante, Menado, Celebes.

I have just finished the translation and publication of Mr. Wallace's "Contribution to the Theory of Natural Selection."

ADOLF BERNHARD MEYER

12, Victoria Road, Kensington, London, W., June 28

Fertilisation of the Barberry

C. K. SPRENGEL, in his *Entdeckte Geheimniss der Natur im Bau und in der Befruchtung der Blumen*, gives an excellent account of the structure of the Common Barberry, *Berberis vulgaris*, and points out how it is visited by insects, and how, upon the touch of an insect's limb or proboscis, the irritable filaments move inwards, and press the opened anthers against the stigma. It is needless to recapitulate the details of structure and movements of a plant so well known, but I venture to think that there is a function and a purpose beyond those which Sprengel's ingenuity has pointed out. Sprengel's great object was to show how insects and flowers mutually help one another, and, consequently, when he had shown that the anther could not shed its pollen on the stigma until the filament was touched by an insect, and that, when so touched, the open anther became pressed against the stigma, he was satisfied. He does not seem to have been fully alive to the wider generalisation made by Mr. Darwin, that this relation of insects to flowers serves the purpose of crossing by fertilising the stigma of one flower with pollen taken from another. At any rate, in this case he has been content with the ingenuity of the apparatus for self-fertilisation through the instrumentality of an insect.

But there are one or two circumstances which seem to show that there is something further in this curious motion of the stamens of the Barberry.

In the first place, each filament only moves when touched at a particular spot near its base, where a very slight touch—*e.g.*, with a human hair—will make it start up. The other stamens remain unmoved, and a bee will frequently visit the flowers and carry off the abundant nectar without moving any stamen at all.

In the second place, after the stamen has moved inwards, which it does rapidly and with a sort of jerk, it soon begins again to move slowly outwards and backwards, and in a short time recovers its original position. Pollen still remains in the anther cells, and the stamen is ready again to jump up towards the stigma on the visit of another insect.

Now these two facts are not explained, if the sole object of the movement of the stamens is self-fertilisation. Why in that case should each stamen move separately when gently touched on its inner side, and why should it return to its original place, instead of remaining with its whole mass of pollen firmly pressed against its own stigma? Why, too, should it move inwards rapidly, and retreat slowly?

But if the object be to enable the insect to carry pollen to another flower, these facts, as well as the remarkable points of structure and function noticed by Sprengel and others, are all explained.

The separate stamen moves when touched on its inner side by the thin proboscis or limb of an insect, in such a way as to leave its pollen on that limb or proboscis, or on the body of the insect, which will then generally be interposed between the anther and the stigma. And the stamen returns to its place after the insect has departed laden with pollen to other flowers, in such a way as that, when more nectar has been deposited and another insect comes and touches it, it may again spring up and deposit some of its remaining pollen on that insect, to be again carried by it to fresh flowers.

If this be so, the function of the whole apparatus is not to cause self-fertilisation, but to enable insects to carry pollen from one flower to another. The case is curious, because at first sight the very remarkable movement of the stamens in this plant certainly looks like an ingenious device for *self-fertilisation*, and as such, an argument against the crossing theory.

Mr. Darwin, to whom I have mentioned this, tells me in confirmation, that the North American Barberries (*Mahonia*) have become so much crossed that it is almost impossible in this country to procure a true specimen of the two or three forms originally introduced. T. H. FARRER

The Corona

I DO not think Dr. Gould's lucid account of his own views could have been misunderstood. I, at least, who replied to him, understood him in the sense in which he has written to you.

The chief question at issue has been, whether there is or not *anything at the sun* (to use Dr. Gould's expression, as, on account of its very vagueness, most suitable), *outside the prominences*. Mr. Lockyer has said *no*; I and others have said *yes*; and Dr. Gould has helped to prove we were right. It has always seemed to me, however, that the photographs taken by Mr. De La Rue and Fr. Secchi, in 1860, had settled the question.

The question relating to matter outside this brilliant appendage, is of less moment. We know certainly that during totality there is *some* light in our atmosphere, and the question where this begins or ends is more interesting to the meteorologist than to the astronomer. But I would invite Dr. Gould's attention to the fact that in the March number of the Astronomical Society's *Monthly Notices*, I have given a simple mathematical proof of the fact that no atmospheric light *can* come in any considerable total eclipse from any region of the sky within seven or eight degrees of the eclipsed sun.

So far as this proof is concerned, I cannot admit that the matter is one of theory at all. But my views as to the *nature of the material* producing this coronal light are not founded on absolutely certain evidence, though the evidence in their favour is very strong indeed. Moreover, I should expect that precisely those appearances would be seen which Dr. Gould regards as tending to show that the faint coronal light arises from something *which is not at the sun*.

But really where a mathematical demonstration of a fact is extant, the consideration of arguments derived from admittedly doubtful evidence seems a mere waste of time. It may as readily be shown that the three angles of a triangle are not equal to two right angles, as that in the Indian or American eclipses atmospheric glare could have been visible within seven or eight degrees of the eclipsed sun.

In the supplementary number of the *Notices* of the Astronomical Society, I hope to give a further explanation of the extremely simple proof on which my views depend; and (because all questions involving considerations of tri-dimensional space are perplexing to most non-mathematicians) I am having a mechanical figure constructed to make the matter clearer, in illustration of papers I hope to read at the next meeting of the British Association, and next November before the Astronomical Society.

RICHARD A. PROCTOR

South Lambeth, June 24

Euclid as a Text-book

THE suggestion of Mr. Levett with regard to the formation of an Association for securing a general reform in the teaching of geometry, is worthy of being at once carried out. Such an association would show how general amongst teachers is the dissatisfaction with the ancient methods, and might lead to more uniformity of practice by securing a free public discussion of the best methods and most suitable terms. There are abundant materials available as the basis of discussion, and no doubt the aid of the most distinguished geometers would be easily secured by the Association, so as to bring about a decision on controvertible points. Several English text-books are already in existence, and there are many good features as well as many defects in all of them. Excellent series of lectures have lately been given on the subject in London and Cambridge, and some of the lecturers have printed very full notes for the use of their students. The syllabuses of Mr. Clifford, and Professor Hirst, are very suggestive.

After an exhaustive discussion, the Association would doubtless be able to secure the publication of a text-book which would have the approval and patronage of all its members. If the readers of NATURE who approve of the plan, would send their names to Mr. Levett, with contributions, if possible, towards expenses of printing, postage, and advertisement, some practical result would soon ensue.

Brixton RICHARD WORMELL

Storms and Fishes

CAN any of your readers give me any information on the following subjects?

1. What is Le Verrier's law of storms?

I asked this question some months ago, but no one replied to it.

2. Have any articles or special works on Poisonous Fishes appeared since Dumeril's memoir on the subject?

I should also be obliged to anyone who can give me information regarding fresh-water fishes that are in the habit of attacking bathers. Don Paez describes such fishes in some of the South American rivers. M.D.

The Scientific Education of Women.

WILL you kindly allow me to add some information to an article which I have just seen in NATURE of June 16, on the Scientific Education of Women? First, however, allow me to correct an error which was made in an article on Lectures to Ladies, which I observed in NATURE some months ago, in which it was stated that the first series of educational lectures to women given under the auspices of any society for such lectures, was given under the direction of the Edinburgh Ladies' Educational Association. The fact is, that the first series of lectures of that kind, in recent years, was given in Liverpool, Manchester, Leeds, and Sheffield, under the auspices of the "North of England Council for the higher Education of Women." These lectures were given in the Autumn of 1867. The subject was Physical Astronomy. Under the auspices of that society, as well as of other societies, many sets of lectures have been given since that time on subjects connected with Physical Science. But I have always regretted, as the writer of your article regrets, that a greater number of the lectures have not been on such subjects, for I have always found that women exhibit a peculiar aptitude for the study of Physical Science. I have also found in my own experience a considerable desire on the part of women for such studies; and I believe that the fewness of such courses of lectures to them is to be put down to the scarcity of people at once competent and willing to teach them such subjects. From all that I have seen there is in my mind no doubt that the desire for true scientific instruction throughout the country, both among women and among men, exceeds the present possibility of supplying that teaching. I called your attention to this fact some months ago, and I believe that we cannot over-estimate its significance.

With respect to the remarks made in your article as to the medical education of women, it may interest your readers to know that Cambridge, which has moved so much in the matter of women's education, has not been behind-hand in this; but that a few weeks ago a petition went up to parliament praying that, in the ensuing legislation for the medical profession, provision might be made to prevent the exclusion of women from that profession. This petition was from resident graduates, and one hundred names were attached, among which were those of two heads of houses, nine University professors, and thirty-eight tutors or assistant-tutors of Colleges.

In your notice of the exhibitions in connection with the lectures to women at Cambridge, you speak of the Cambridge higher examinations for women. These examinations, which were instituted last year for women over eighteen years of age, were suggested to the University by a memorial presented by the North of England Council for the Higher Education of Women, a body to whose exertions the whole of this cause is deeply indebted. JAMES STUART

June 22

ILLUMINATION OF THE SEA

THE following is derived from the *Kölnische Zeitung* of June 19:—

"Gulf of Siam, April 11

"Last night, between two and three o'clock, I had the opportunity of witnessing an illumination of the sea of the most peculiar kind. It had become quite calm, after a sharp breeze which had sprung up from the N.N.W., caused by a passing storm in the distance. Heat-lightning was still very frequent in the west horizon, and the sky was covered with light clouds, through which the moon shone rather brightly. We took in sail and set the engines going. I then noticed in the water large white flakes which I had at first taken to be reflections of the moon; they were about a fathom in diameter, apparently lustreless, and of no particular shape, like objects seen lying deep in the water. By the rising and falling of the sea's surface these flakes floated off to a short distance from the ship without imparting any noticeable increase of brightness to the water illuminated by the moon's rays. After steaming further forward for six or seven knots, a most wonderful spectacle presented itself. On both sides obliquely in front of us, long white waves of light were seen floating towards the ship, increasing in brightness and rapidity till at last they almost disappeared, and nothing was observed but a white lustreless, whirling (*schwirrendes*) light upon the water. After gazing for some time it was impossible to distinguish between water, sky, and atmosphere, all which were but just now clearly distinguishable, and a thick fog in long streaks appeared to be driving upon the ship with furious swiftness. The phenomenon of light was somewhat similar to that which would be produced by the whirling round of a ball striped black and white so rapidly that the white stripes seem to be lost and blended with the dark ones. The light was just as if we were enveloped in a thick white fog. The direction of the waves of light upon the ship was always on both sides obliquely from the front. The phenomenon lasted about five minutes, and repeated itself once more afterwards for about two minutes. Without doubt, therefore, shoals of small creatures in the water were the cause of this luminosity, and the waves of light find their cause, according to my conviction, in the white flakes above described. Yet their moderate velocity of $1\frac{1}{2}$ geog. mile per hour, and the weak light at first emitted by each flake, so weak as not to influence the tint of the surface-water, does not seem calculated to call forth a phenomenon of such magical effect as the one described. The luminous appearance commonly seen in the wake of a ship, or in water disturbed by oars or rudder, is not to be compared with such a phenomenon as the above. In the former the light is lustrous, glaring green and blue, like phosphorus, often very splendid in deep clear water, mingled with a reddish white foam. We saw a beautiful instance of this kind one night, in perfectly still and smooth water, in a lonely bay of Nipon. It was pitch dark and perfectly quiet, when a heavy shower of rain came on, in large but not dense drops. Every drop as it struck the water became illuminated, little drops of fire sprang up in the air, and a little luminous circle formed itself. It seemed as if the bay was suddenly filled with little flowers of fire. This phenomenon was almost immediately dissipated by a puff of wind."

FLIGHT.—FIGURE OF 8 WAVE THEORY OF WING MOVEMENTS

IN the Proceedings of the Royal Institution of Great Britain for March 1867, Dr. J. Bell Pettigrew, F.R.S., the distinguished curator of the museum of the Royal College of Surgeons of Edinburgh, announced the startling discovery that all wings whatever—those of the insect, bat, or bird—were twisted upon themselves structurally, and that they twisted and untwisted during their action—that in short they formed *mobile helices* or *screws*. In June of the same year (1867), Dr. Pettigrew, following up his admirable researches, read an elaborate memoir "On the Mechanism of Flight" before the Linnean Society of London, wherein he conclusively proves, by a large number of dissections and experiments, in which he greatly excels, that not only is the wing a screw structurally and physiologically, but further that it is a reciprocating screw. He shows, in fact, that the wing, during its oscillations, describes a figure of 8 track similar in some respects to those described by an oar in sculling. This holds true of the vibrating wing of the insect, bat, and bird, when the bodies of these animals are artificially fixed.

When, however, the creatures are liberated, and flying at a high horizontal speed, the figure of 8, as he points out, is curiously enough converted into a wave track, from the wing being carried forward by the body, and from its consequently never being permitted to complete more than a single curve of the 8. This is an entirely new view of the structure and functions of the wing, and one fraught with the deepest possible interest to the aeronautical world. It promises to solve everything. Dr. Pettigrew's remarkable discovery has received an unlooked-for confirmation within the last few months at the hands of Professor Marey, of the College of France, Paris. This gentleman, whose skill in applying the graphic method to physiological inquiry is unequalled, has succeeded in causing the wing of the insect and bird to register their own movements, and has established, by an actual *experimentum crucis*, the absolute correctness of Dr. Pettigrew's views. Professor Marey's mode of registering displays much ingenuity, and is briefly as follows:—"A cylinder revolving at a given speed is enveloped by a sheet of thin paper smeared with lamp black, and to this the tip of the rapidly vibrating wing of the insect is applied in such a manner as to cause it to brush out its track on the blackened paper, which it readily does. A similar result is obtained in the bird by fixing a registering apparatus to the wing and causing the bird to fly in a chamber. In this case the registering apparatus is connected with the cylinder by means of delicate wires, and the registering is effected by means of electricity. In both cases the figure of 8 and wave movements, originally described and figured by Dr. Pettigrew, are faithfully reproduced. The way of a wing in the air has hitherto been regarded as a physiological puzzle of great magnitude; and well it might be, since some insects (the common fly for example) vibrate their wings at the almost inconceivable speed of 300 strokes per second, that is, 18,000 times in a minute!

It should be added that though Professor Marey endorses Dr. Pettigrew's view as to a figure of 8 movement, and has recently admitted his priority in that observation, he is yet by no means of the same opinion as Pettigrew as to the explanation of the mechanical effect of the movements and the influence of the bird's weight. Pettigrew maintains that the wings act as inclined planes in such a way that the bird actually rises by its own weight. Dr. Marey will not admit this at all, and is at issue with the Scotch anatomist on some other matters of moment, as he recently informed the writer. The beautiful and ingenious experiments which Dr. Marey is now carrying on will place these matters beyond conjecture by the light of experiment.

A FALL OF YELLOW RAIN

ON the 14th of February a remarkable yellow rain fell at Gênes. The following details respecting it are given in a letter addressed to M. Ad. Quetelet by M. G. Boccardo, director of the Technical Institute of Gênes, who examined it in concert with Dr. Castellani, professor of chemistry. The quantitative analysis gave the following results:—

Water	6·490	per cent.
Nitrogenous organic substances	6·611	,,
Sand and clay	65·618	,,
Oxide of iron	14·692	,,
Carbonate of lime	8·589	,,

Observed narrowly under the microscope, the presence was revealed of a number of spherical or irregular ovoid substances of a cobalt blue colour; corpuscles similar to the spores of *Peziza or Permospora;* spores of *Demaziaceæ* or *Spheriaceæ;* a fragment of a *Torulacea* (?); corpuscles of a pearly colour, concentrically zoned, probably small grains of fecula; gonidia of lichens; very scarce fragments of *Diatomaceæ;* spores of an olive brown colour; a few fragments of filaments of *Oscillaria*, *Ulothrix*, and *Melosira varians;* a fragment of *Synedra;* a peltate hair from an olive leaf. If, instead of collecting the earth on the morning of the 11th, when it had already been subjected to the action of rain falling for several hours, I had been able (writes M. Boccardo) to observe the phenomenon during the night, at the moment when it was produced, it is very probable that the microscope would have shown the existence of several kinds of Infusoria, as has been the case in several similar instances.

The author notes that the direction of the wind at Gênes during the night of the 13th and 14th was from the south-east, and without being exactly a hurricane as on the preceding few days, was still very strong. The temperature, previously exceptionally low, had risen, and probably did not fall during the night below $+4°$ R. ($5°$ C. or $41°$ F.) The journals state that on that date a tempest devastated the coasts of Sicily. M. Boccardo, following P. Denza, proposes the theory that the dust came from the coast of Africa. "We ought not to forget," he writes, "that according to Maury's theory of the circulation of the atmosphere, these clouds of dust may well have travelled a long distance before touching the soil of Italy, coming from beyond the Atlantic, like those which in 1846 spread from Guiana to the Azores, over the south of France and the whole of Italy."

RELICS OF NON-HISTORIC TIMES IN JERSEY

CONSERVATION *v.* DESTRUCTION

ON the 18th of May information was received from Jersey of the partial demolition of some tumuli, hitherto undescribed in that island; and, accordingly, two gentlemen, interested in the conservation of all ancient monuments, resolved to make a tour of inspection of the pre-historic remains in Jersey without delay, and the following is the result of the inspection:—The time was necessarily brief, occupying only two days, the party arriving at Jersey at 11 A.M. on the 19th, and leaving the island at 6.45 A.M. on the 21st. A summary of the route taken may be useful to tourists and others who may wish to visit all the pre-historic stone monuments in Jersey, as far as they are known at present. Leaving St. Helier's by the St. Aubin's road, the first attraction is the Ville Nouaux Cromlech, not far from the first martello tower. This structure was examined last year by leave of M. de Quetteville, the proprietor, and described at the time.

As now exposed to view, this cromlech appears to be an elongated *allée couverte*, nearly due east and west, measuring 35 feet in length. Its sides, about four feet apart, are as nearly as possible parallel, although there are indications of the avenue being narrowed towards its eastern extremity, as we should expect to find. The side blocks of stone average from 4 to 5 feet in height, and number eleven on the northern and seven on the southern side, the western end being closed by a fine single slab. The interstices between these blocks are roughly filled up with irregularly shaped smaller stones, evidently built in to prevent the exterior earth and soil of the superimposed tumulus from falling into the sepulchral grotto.

There must have been formerly at least nine cap-stones; of these, two have been removed, as observed above, whilst the whole fabric appears to have been tilted, with an inclination to the south, probably caused either by the unequal pressure of the accumulated sand-drift on the northern side, or by the removal of the ballast from its southern supports. It is difficult to determine whether all the cap-stones are in their original positions, or whether some of them have not slipped between the side blocks from their summits.

Several urns, tulip shaped, &c., with a cylindrical stone muller, were brought back to Guernsey from this cromlech, and are now deposited in Mr. Lukis's museum.

Not far to the north of this spot is a semicircle of stones, which presents a suspicious appearance.

It is much to be wished that the tenant of this field would prevent the causes of the filthy state in which this cromlech is at present. The stones themselves have not been disturbed since the last exploration.

Entering St. Laurence's parish, to the right of the road, on the hill above the vineries, is La Blanche Pierre, a menhir which is fortunately still preserved. The route is next taken to the north-west, through St. Peter's parish to St. Ouen's, and the small hamlet of Trodais. Here the party visited M. Lefeuvre, who in the course of agricultural operations, has removed a large portion of tumuli on his property, and who, six years ago, found within one of them, and has in his possession, a remarkable cinerary urn with four handles, evidently for suspension. The upper portion of this urn, which is hand-made, not turned, is likewise decorated with an ornamental border, consisting of horizontal lines, so arranged as to form three triangles between each handle. It is of a different and later type than the urns discovered in the cromlechs of these islands. M. Lefeuvre accompanied his visitors to the sites of the tumuli. These curious mounds are in two groups, one group being called *Les Hougues de Millais*, on one spur of the hills overlooking L'Etac and St. Ouen's bay, to N.W. of *La Robeline*, and the other on a similar spur to the S.E. of the former, about 800 yards distant, in a line with St. Ouen's windmill; these last are called *Les Monts de Grantez*. A portion only of one of the *Hougues* remains, and exhibits a series of cap-stones, five in number, of which four remain, supported by a dry-walling of smaller slabs, forming a tunnel about 18 feet long, which lies east and west, and was blocked at either end with a broad stone, of which the west one alone is *in situ*. It presents an exact parallel to the *Creux des Faias*, which existed till lately in St. Peter's parish, Guernsey, a few hundred yards west of the menhir at Les Paysans; but which has been swept entirely away. A granite muller was picked up here by the visitors, which also resembled, in a remarkable manner, a similar one picked up but a day or two before by the same gentleman, on the site of the *Creux des Faias*, in Guernsey, showing an identity of manufacture and a contemporaneity of construction of the tumuli in both islands.

Leaving Les Hougues, and after visiting Les Monts de Grantez, St. Ouen's church, which is being magnificently restored, was examined, and a worked stone of the Neolithic period picked up in the churchyard. Pursuing the circuit of ancient remains, the route descends towards the sea by St. Ouen's pond, where, in the Val de la Mare, St. Peter's parish, are *Les Trois Roches*, in all probability a portion of a cyclolith. Two only are upright, the third lying prone at a little distance and not visible at first sight, until one approaches close to it. The ground being marshy it has formed a pit for itself. The upright stones have been apparently worked into shape on their summits, whilst their sides are almost polished from cattle rubbing against them. The new road is now traversed through the western portion of St. Brelade's parish, between the dreary *dunes* of *Les Quenvais*, and ascending by *La Pulente* on to the hills of La Moye; a kitchen-midden is to be found at the summit of the ascent, where the soil has been scarped in the formation of the road, a mass of limpet, ormer, mussel, and other shells, at some feet in depth below the surface of the original soil.

The famous menhir of Le Quesnel, which stood so picturesquely to the south of this spot this time last year, has fallen a victim, and in its place a large quarry yawns; but in Le Marais, close by, is a portion of a circle, and an alignement, in connection with the former menhir, is still to be traced. Close to Moye signal staff a natural cropping up of the rock presents a striking resemblance to a cromlech and circle round it. About half a mile from Le Quesnel, and directly above La Corbière Point, is a fine single stone Dolmen called La Table des Marthes, beneath which were found some bronzed implements many years since.

Over the granite quarries of La Fosse Vaurin, is a curious natural work which, aided by the hand of man, presents the appearance of two basins with a channel for emptying one, whilst the fissures to the east resemble a cross, the work, perhaps, of some hermit in mediæval times. Several mullers, worked stones, &c., were found in the locality during this brief visit, and brought back to Mr. Lukis's collection. A seven miles' drive brings one back to St. Helier's. This day's visitation occupied from 11 A.M., until 9 P.M., but much time was spent in sketching and measuring, searching for stone implements, &c. The find for the day was tolerably good, viz.:—Ville Nouaux Cromlech, 1; Les Hougues de Millais, 1; St. Ouen's churchyard, 1; Les Trois Roches, 3; La Moye, 5 stone implements.

S. P. OLIVER, Lieut. R.A.

40, Hauteville, Guernsey

SOUNDINGS AND DREDGINGS BY THE UNITED STATES COAST SURVEY

IN the office of the Coast Survey at Washington there are about 9,000 specimens of various kinds of marine animals which were brought up by the sounding lead from the sea-bottom, in the region between the shore of Florida and adjacent States and the outer edge of the Gulf Stream, and descending to a depth of 1,500 fathoms nearly. The dredge has been but comparatively little used along the coast of the United States, and that so many specimens were collected by the lead alone is due to the persevering care of the late superintendent of the survey, Prof. A. D. Bache, and to the instructions which he gave to the hydrographical officers. Of course, specimens brought up by the lead can include the smaller animals only, such as Foraminiferæ, Diatomaceæ, and such like; for the larger animals, the dredge must be employed.

The work thus begun has been resumed by the present superintendent of the Coast Survey, Prof. B. Peirce. The surveying parties are instructed to take observations of the depth, velocity, and direction of the Gulf Stream, the temperature and density of the water at different depths, and of the Fauna from the surface down to the bottom. By these researches we may hope that our knowledge of the phenomena of the Gulf Stream will be increased, particularly as regards its powers of transportation from shallow to deeper water, or along its bed, besides its action in forming deposits in particular localities, and its possible influence on the growth of coral reefs on its shores.

The first operations under the new direction were carried on between Key West and Havana, along the route now occupied by a telegraph cable. Dredgings were made at depths varying from 90 to 300 fathoms, and yielded Crustaceans, Annelids, Mollusks, Radiata, Foraminiferæ, Sponges, a single vegetable specimen, being a minute alga, *Centroceras clavulatum*, and "a number of nodules of a very porous limestone, similar in colour and texture to the limestone forming the range of low hills along the shore of Cuba, but composed apparently of the remains of the same animals which were found living." Among these Deltocyathus, Caryophyllia, and Pteropods were recognised in the stone, and found in various stages of fossilisation.

At the end of a descriptive list of the specimens collected during the cruise, M. de Pourtales remarks :—"It would be premature to compare this deep-sea Fauna with the animals inhabiting the regions of lesser depth on the coast of Cuba or Florida. In the first place, many of the smaller forms—such, for instance, as the Bryozoa or the Hydroid polyps of those shores—are not yet sufficiently known to enable us to say if any of the species dredged exist in any other than the abyssal region. Then, a very different value must be assigned to the different classes of animals under examination. Thus, the dead shells must be left out of the question, at least the smaller ones, for they may have dropped with the excrement of fishes, or, in the case of Pteropods, have sunk from the surface after the death of the animal. The Crustaceans and Annelids being abundant and generally sedentary, will, when better known, afford good characteristics of the regions of unequal depth. The same remark applies to the sponges and the Foraminiferæ; the great abundance of the latter and the ease with which they can be brought up by the sounding lead render them particularly useful."

From this it will be understood that the United States Coast Survey is in good hands, and may be expected, when the time comes, to take part in the suggested dredging expedition all across the Atlantic, when England and the States, after accomplishing each a half, are to meet and shake hands in mid-ocean.

NOTES

PROFESSOR HENRY, the President of the American Academy of Sciences, and Director of the Smithsonian Institution, is now in this country *en route* to the Continent to attend the meetings of the International Commission on Standards.

WHEN presiding over the distribution of prizes for the Faculty of Arts and Laws at University College, London, on Friday last, the Bishop of Exeter made some admirable remarks on the nature of a true system of education, and of the places which ought to be occupied by classics, mathematics, and natural science, and the proper method of teaching them. In all true teaching a scientific method is indispensable; it is because this scientific method has been applied to instruction in Greek and Latin, that such good results have been obtained in this department of education. The introduction of scientific teaching has not hitherto met with the same success because it has not been carried out in the same spirit. In very many instances, those who are endeavouring to promote the study of natural science as a part of education, have made the great mistake of omitting altogether that which is essential to true study, namely, scientific method. The reason why the teaching of the natural sciences still hangs back in our public schools is, in great measure, the unscientific method in which science has been taught by many. To form a part of real education, the study of science must be pursued in the same rigorous manner as that of classics or mathematics; it will then prove as hard work to the learner, and the result of its introduction must be most beneficial. While the exclusive study of mathematics must fail as a complete discipline for the understanding, and the great mathematician may be uncultivated as a man, it is very rarely that you see such a result in the student of external nature; therefore, this study must rank by the side of the other, and must hold a place in no way inferior to it. The practical importance given to these remarks by the experience of Dr. Temple at Rugby, ought to make them carry great weight with all teachers of science.

DR. HENRICI has been elected by the Council of University College, London, Professor of Mathematics, in the place of Dr. Hirst, who resigned the professorship, on his appointment to the Assistant-Registrarship of the University of London. Dr. Henrici had acted as Prof. Hirst's assistant during the whole of the session just ended. He had pursued his mathematical studies at Carlsruhe under Professor Clebsch, and subsequently at Heidelberg, where he attended Prof. Hesse's lectures on mathematics, and those by Prof. Kirchhoff on theoretical physics. While at Heidelberg he took his degree of Doctor of Philosophy in the highest grade, and the Philosophical Faculty of the University considered the dissertation which he wrote on that occasion to have so high a scientific value, that they recommended the government of Baden to recognise its importance by conferring upon Dr. Henrici a special public distinction. Dr. Henrici subsequently prosecuted his studies at Berlin and Kiel, and then came to England, where he has resided nearly five years.

THE completion of the deep-sea cable between Falmouth and Bombay was celebrated last Thursday evening by an entertainment given by Mr. Pender, chairman of the British-Indian Submarine Telegraph Company, at which royalty largely assisted. Complimentary messages were exchanged between the Viceroy of India and the President of the United States, the distance of 8,442 miles being accomplished in forty minutes; between the Prince of Wales and the Khédive, the Prince of Wales and the King of Portugal, the Prince of Wales and the President of the United States, and the Prince of Wales and the Viceroy of India. This is the first instance of direct telegraphic communication between India and America. The comic side of telegraphic communication was presented by the message between the Prince of Wales and the Viceroy, which, though despatched soon after twelve at night, and only nine minutes on its way, reached Lord Mayo at five in the morning, when his lordship was, naturally enough, fast asleep. What will be the result when the earth is completely girded with a telegraphic cable, and a message is sent to the antipodes? The question between night and day will be expanded to one between to-day and tomorrow, to say nothing of yesterday.

THE Royal Commission on Scientific Instruction and the Adancement of Science has held two meetings since our last issue.

THERE will be an election at Magdalen College, Oxford, in October next, to six Demyships and one Exhibition. Of the Demyships, one will be mathematical, one in natural science, four classical. The Exhibition will be in natural science. It is necessary that candidates for the exhibition should prove to the satisfaction of the electors that they cannot be supported at college without such assistance. Evidence on this point will be considered as confidential. No person will be eligible for the Demyships who shall have attained the age of twenty years, and (in the case of candidates in mathematics and natural science) who is not sufficiently instructed in other subjects to matriculate as a member of the college. The stipend of the above Demyships and Exhibition is 75*l.* per annum, inclusive of all allowances; but there are tenable with the Demyships certain College Exhibitions, which raise their annual value, on an average, to about 83*l*. They are tenable for five years. Testimonials of good conduct will be required, and a certificate of birth and baptism, which must be presented to the President on Monday, the third day of October, between the hours of three and six, or eight and nine P.M. The examination will commence on the following day. Particulars relating to the examinations in the various subjects may be obtained by applying to the senior tutor. No entrance fees or caution money are required by the college. The University fees payable on matriculation amount to 2*l*. 10*s*.

IT is refreshing to learn that that reverend and tory institution, St. John's College, Oxford, has just elected to a fellowship a devoted physical investigator, in the person of Mr. Bosanquet. This election is important, not only as a recognition of natural knowledge, but also of the principle of research as against that of mere education.

CONSEQUENT on the death of the Rev. Dr. Luby, one of the Senior Fellows of Trinity College, Dublin, the Rev. Mr. Jellett, B.D., President of the Royal Irish Academy, has been co-opted a Senior Fellow. It is understood that the Professorship of Natural Philosophy held by Mr. Jellett will be given to the Rev. R. Townsend, A.M., author of the "Modern Geometry of the Point, Line, and Circle."

THE Minister of Public Instruction in Italy has promised a grant of 1,600 *lire* towards the expenses of instituting a laboratory of cryptogamic botany in Pavia; and it is hoped that a contribution will also be received from the Minister of Agriculture.

THE death of Sir James Simpson has been followed by another heavy loss to medical science in that of Professor Syme, who died on Sunday last, at the age of seventy. Mr. Syme was for a short time Professor of Surgery in University College, London; for a much longer period he occupied the chair of Clinical Surgery in the University of Edinburgh, which he resigned only quite recently to his son-in-law, Mr. Joseph Lister. He was a voluminous writer on surgical subjects, many of his works being held in very high reputation.

THE *Field* suggests that the drought of the summers of 1868 and 1870 is connected with the rapid increase of drainage in this country, the average summer rainfall having been greatly reduced from 1860 to 1870. Our contemporary also expresses an opinion, in which we cordially concur, that a needless alarm has been raised as to the prospects of the corn harvest, as shown in the rise of 10*s*. to 12*s*. a quarter in wheat at Mark Lane. The harvest of 1868 is the finest on record; and we hope to see the prediction of our contemporary fulfilled, that "the cereal crops in this country will, on the whole, turn out favourably."

NOW that so many, both Londoners and their country friends, are flocking to the national botanic garden at Kew, we may call attention to Prof. Oliver's "Guide to the Royal Botanic Gardens and Pleasure Grounds, Kew," which has now reached its twenty-fifth edition. It is a *multum in parvo* of value and interest far beyond the purpose for which it is designed; indeed we do not know where else, in so small a compass and at so low a price, to meet with so much and varied information respecting the vegetable products of different countries, their economic purposes, and their geographical distribution, illustrated with exceedingly well-drawn woodcuts.

IN a paper in the *Bulletins de la Société Vaudoise*, No. 62, Dr. C. Nicati gives a *résumé* of various researches respecting the peculiar red snow which occasionally falls in the Grisons. Some of this snow fell, mingled with common snow and rain, during a violent storm from the south-west on the morning of January 15th, 1867, in various places. The chemical analysis of the melted snow demonstrated the presence of minute quantities of sulphate of lime or gypsum, sulphate of magnesia, organic matters, chlorine, and iron; and microscopic examination detected vegetable fibre, pollen, spores, with here and there diatoms and small crystals. The colour varies from brick red to a pale yellow. This snow is quite distinct from the red snow of the upper Alpine regions, which owes its colour to the presence of the minute plant, *Protococcus nivalis*. After discussing various theories respecting its origin, Dr. Killias expressed his opinion that it is the dust of the desert of Sahara, transported by a sirocco, which gives the colour to the snow of the Grisons. Dr. Nicati gives many interesting particulars, with analyses, of the Algerian sirocco dust, and of the mud-rain in Naples and Sicily; and Professor C. Cramer states that he has discovered, both in the sand of the Sahara and in the red snow of the Grisons, particles of vegetable organisms (especially polythalamia) and minute fragments of animal origin, such as wool, hair, &c. He considers the presence of gypsum in the red snow an incontestable proof of its containing matter conveyed from the desert of Sahara

PROFESSOR GERARDIN has recently communicated to the Council of the "*Société d'encouragement pour l'industrie nationale*" the results of his efforts to purify the waters of the Croult, a small river which, rising at Louvres, passes through Gonesse, Arnouville, and flows through St. Denis, ultimately falling into the Seine. The stream was poisoned by the drainage from the starch manufactories. The principle on which M. Gerardin proceeded was that water in which weeds and shell-fish cannot live was infected and poisoned. The potatoes from which the starch was made contain 75 per cent. of juice, which itself contains 7 per cent of albumen. The water issuing from the factory is clear, reddish, and inodorous; in motion, it forms coherent masses of coagulated albumen. The river deposited in its course masses of whitish, pitch-like substance, without consistence. The surface was covered with white froth; the mud black and stinking, while the water had a strong odour of sulphuretted hydrogen. M. Gerardin recognised the white masses deposited by the waters as the "baregine" characteristic of the sulphurous waters of the Pyrenees. When the works stop, this "baregine" putrefies, and infusoria are developed in abundance. M. Gerardin thought the best method of remedying the unwholesome state of the water would be to destroy the albumen by the simultaneous action of the air, clay, and the organic fermenting agents always contained in cultivated ground, and he determined to make the waters pass over a soil well drained. The factory of M. Boisseau, at Gonesse, consumed in a day 400 hectolitres (sacks) of potatoes, weighing 28,000 kilog. (27½ tons), and containing 21,000 kilog. of juice, carried off by 130,000 litres of water (say 28,500 gallons); these waters are spread over a field whose area is 500 yards square, in which are placed drains at 6 feet distance from each other, and 2 feet deep. The arrangement has perfectly succeeded. Weeds grow in the Croult from Louvres to St. Denis: *Limnæus* and *Planorbis* find their abode in these weeds, the "baregine" has disappeared, the sulphuretted hydrogen odour is entirely gone, and the water is sweet and limpid.

A GOOD tabular arrangement of the Natural Orders of plants is very much wanted by botanical teachers, where the alient diagnostic characters of allied orders are presented to the eye at a glance. That this desideratum is entirely supplied by Dr. Griffith's "System of botanical analysis applied to the diagnosis of British natural orders," we cannot altogether affirm, as each teacher will probably find it vary in some respect or other from his own ideas of the best mode of classification. We can, however, safely recommend it as a useful help to beginners in getting over the difficulties of systematic botany.

FACTS AND REASONINGS CONCERNING THE HETEROGENOUS EVOLUTION OF LIVING THINGS*

IN all ages it has been believed by many that Living things of various kinds could come into being *de novo*, and without ordinary parentage. Much difference of opinion has, however, always prevailed as to the kinds of organisms which might so arise. And, although received as an article of faith by many biologists—perhaps by most—in the earlier ages, this doctrine or belief has, in more recent times, been rejected by a very large section of them. Definitely to prove or disprove the doctrine in some of its aspects is a matter of the utmost difficulty, and there are reasons enough to account for the wave of scepticism on this subject, which has been so powerful in its influence during the last century. The notions of the ancients were altogether crude, and founded upon insufficient proofs. It was not in their power to settle such a question; and when the inadequacy of the evidence on which they had relied became known, then much doubt was thrown also on the truth of the conclusion at which they had arrived. All this was natural enough. When, therefore, about a century ago, the rude microscopes of the time began to reveal a multitude of minute organisms whose existence had been hitherto unsuspected; when more facts became known concerning the various modes of reproduction amongst living things; and, above all, when the philosophical creeds of the day were supposed to be irreconcilable with such a doctrine, then a growing scepticism in the minds of many gradually developed into an utter disbelief in the possibility of the occurrence of what was called "spontaneous generation."

This was the state of things anterior to and during the time of the celebrated controversy between the Abbé Spallanzani and John Needham. Then it was that the former of these two champions, with the view of accounting for phenomena which would otherwise have necessitated his admission of the doctrine which he rejected, recklessly launched upon the world the *hypothesis* that multitudinous, minute, and almost metaphysical "germs" existed everywhere—ready to burst into active Life and development whenever they came under the influence of suitable conditions. Armed with this all-powerful *Panspermic* hypothesis, Spallanzani argued against the conclusions of Needham. His views on this subject were supported by the still more extravagant theories of Bonnet. The doctrine of "*L'Emboîtement des germes*" was the production of an unbridled fancy, and might, perhaps, never have been elaborated, had not the Leibnitzian doctrine concerning "Monads," as centres of force and activity, been already in existence, and at the time all-powerful in the philosophical world.

The controversy which was initiated by these two pioneers in microscopical research they were unable to terminate—the enigma which they sought to solve has, since their time, still pressed for solution, and still the tendency has been to solve it after one or other of the modes by which they attempted to account for the occurrence of the phenomena in question. It is and has been contended, on the one hand, that Living things can originate *de novo*, and without ordinary parentage; it is contended, on the other, that this is impossible—that every Living thing is the product or off-cast of a pre-existing Living thing, and that those which appear to arise *de novo* have, in reality, been produced by the development of some of the myriads of visible or invisible "germs" which pervade the atmosphere.

Now it is obvious, that of these two opposing doctrines, the one must be true and the other false: either Living beings can originate *de novo*, or they cannot. So long as any doubt remains upon this subject, we have to confess our ignorance concerning one of the very first principles of Biology. In the whole domain of Science, moreover, it is scarcely possible to propose a question which is more replete with interest than that which asks whether Living things can be evolved *de novo*. If settled in the affirmative, what light will be thrown upon the past and present history of our globe! How must our notions concerning Life, health, and disease be influenced in one way or the other by its solution!

Without entering into the history of the long controversy which has taken place upon this subject—details of which may be found in the works of Pouchet* and Pennetier,† and in the writings of Pasteur‡—I shall, before describing my own experiments and their results, merely relate as briefly as possible what conclusions have been come to concerning the degree of heat to which inferior organisms may be subjected with impunity, and what temperature, on the other hand, has been invariably found to be fatal to them. Fortunately there is at present much unanimity of opinion on this subject. As a result of numerous investigations which have been communicated to the French Academy, and to the Société de Biologie during the last ten years, we find that both the advocates and the opponents of heterogeny are, within certain limits, pretty well agreed on this most important aspect of the question. The many disbelievers and opponents of heterogeny who took part in these investigations, naturally desired that the power possessed by inferior organisms, both animal and vegetable, of withstanding the destructive influence of high temperatures, should be shown to be as high as possible. We may, therefore, with much safety, assume that the limits of vital resistance could not then be shown to be higher than that which these experimenters were compelled, after frequently repeated investigations, to ascribe to such inferior organisms.

In *dry air* or in a vacuum, organisms are capable of withstanding a notably higher temperature than when they are immersed in fluid. According to the direct observations of M. Pasteur, the spores of certain fungi belonging to the family *Mucedineæ*, seem to possess this tenacity of life to a very great extent; but even these, he says, though they still remain capable of germinating after having been raised, for a few minutes in dry air or *in vacuo*, to a temperature of from 120° to 125° C., lose this power absolutely and entirely after an exposure for half an hour, under similar conditions, to a temperature varying from 127° to 130°C. And the labours of the commission (consisting of the following members—MM. Balbiani, Berthelot, Broca, Brown-Séquard, Dareste, Guillemin, and Ch. Robin) appointed in 1869 by the Société de Biologie, to inquire into the subject, led them to the conclusion that the lower animals which were the most tenacious of life§—the rotifers, the "sloths," and the anguillules of tufts of moss or lichen—succumbed at even a much lower temperature than this. In dry air or *in vacuo*, therefore, we may look upon the temperature of 130°C. for thirty minutes, as marking the extreme limit of vital endurance under such conditions, so far at it has been hitherto possible to fix such a limit. There is, at present, no evidence forthcoming to upset this conclusion. When immersed in *fluids*, however, the power possessed by the inferior organisms of resisting the destructive influence of heat is not nearly so great. Comparatively few, whether animal or vegetable, have been found capable of resisting a temperature of 75°C.; and with regard to that of 100°C., it has been admitted, by MM. Claude Bernard and Milne-Edwards, by M. Pasteur, and by all the other most influential opponents of the doctrines of heterogeny, that such a temperature, even for one minute, has always proved destructive to all the lower organisms met with in infusions‖—so far as these had been made the subjects of special and direct experimentation. And, amongst all the diversity of form presented by the lowest Living things, there is so much of uniformity in property—living matter, as we know it, agrees in so many of its fundamental characters—that biologists and chemists alike may feel a reasonable assurance as to the probable universality of any such rule which has been proved to hold good for a very large number of organisms, more especially when, amongst this large number of cases, no exceptions have been encountered.

Practically, however, it will be found that, in order to appreciate the bearings of the experiments which I shall have to relate, it will be necessary for us more especially to know what are the limits of vital resistance to high temperatures, possessed by *spores* of Fungi on the one hand, and by *bacteria* and *vibrios* on the other.

I am not aware of any experiments tending to show that *spores* of Fungi can survive after exposure for even a few seconds in fluids raised to a boiling temperature (100° C.); whilst, on the

* This paper was originally intended for presentation to the Royal Society, but it was finally not presented, when I understood that, owing to the accumulation of many papers and other causes, no evening could be allotted on which it might be read and discussed. Its appearance *in extenso*, and at once, was thought preferable to the reading of its mere title before the Royal Society, with the probability of a very considerable delay in its publication. —H. C. B.

* Hétérogenie, Paris, 1859. † L'Origine de la Vie, Paris, 1868.

‡ Annales de Chimie et de Physique, 1862.

§ This extreme tenacity of life is perhaps due in part to the chitinous integument with which such animals are provided.

‖ It is quite fair to make this limitation, since we are only concerned with the origin of such organisms. Seeds of higher plants, provided with a hard coat, may—especially after prolonged periods of desiccation—germinate even after they have been boiled for a long time in water.

other hand, there is the concurrent testimony of many observers to the fact that, after such exposure, germination would never take place, because the spores were no longer living. This was the result obtained in many experiments made by Builiard, and related in his "Histoire des Champignons." Mere contact with boiling water was found sufficient to prevent germination; and H. Hoffmann* similarly ascertained that an exposure for from four to ten seconds to the influence of boiling water sufficed to prevent the germination of all the fungoid spores with which he experimented. The experience of other observers has been similar to that above quoted, and amongst these we may cite M. Pasteur himself. Speaking of his experiments with boiled milk in Schwann's apparatus, M Pasteur says:—"Je n'ai jamais vu se former, dans le lait ainsi traité autre chose que des Vibrions et des Bacteriums, *aucune Mucédinée, aucune Torulacée, aucun ferment végétal.* Il n'y a pas de doute que cela tient à ce que les germes de ces dernières productions ne peuvent résister à 100° au sein de l'eau, ce que j'ai d'ailleurs constaté par des expériences directes."†

The evidence which we at present possess concerning the tenacity of life displayed by *bacteria* and *vibrios* in fluids whose temperature has been raised, is just as decisive as that concerning the spores of fungi. M. Pouchet's observations have lead him to believe that vibrios, in common with all the kinds of ciliated Infusoria, are killed by raising the temperature of the fluid which contains them to 55° C. M. Victor Meunier, also, never found any of these organisms alive after they had been similarly subjected to a temperature of 60° C. I have myself invariably found that vibrios were not only killed, but were broken up and more or less disintegrated, after the fluid had been boiled for even one minute. There is every reason also to believe that an exposure to similar conditions kills their less developed representatives—the primordial monads and bacteria. With reference to these organisms, however, one caution is necessary to be borne in mind by the experimenter. The movements of monads and bacteria may be and frequently are of two kinds. The one variety does not differ in the least from the mere molecular or Brownian movement, which may be witnessed in similarly minute non-living particles immersed in fluids; whilst the other seems to be purely vital—dependent, that is, upon their properties as living things. These vital movements are altogether different from the mere dancing oscillations which non-living particles display, as may be seen when the monad or bacterium darts about over comparatively large areas, so as frequently to disappear from the field of the microscope. After an infusion has been exposed for a second or two to the boiling temperature, these vital movements no longer occur, though almost all the monads and bacteria may be seen to display the Brownian movement in a well-marked degree. They seem to be reduced by the shortest exposure to a temperature of 100°C., to the condition of mere non-living particles, and then they become subjected to the unimpaired influence of the physical conditions which occasion these molecular movements.

Such is the evidence existing as to the power of resisting the destructive influence of heat, manifested by the organisms about which we are at present most interested. It is certainly harmonious enough with our ordinary experience, and is, therefore, not difficult for us to believe. Eggs of higher animals containing an embryo may fairly enough be compared with the lower organisms of which we have been speaking, so far as the matter of which they are composed is concerned; and knowing the profoundly modifying influence of water at a temperature of 100° C. upon the comparatively undifferentiated matter of the embryo and of the egg—and also, we may add, even upon the differentiated tissues of the parent fowl—need we wonder much that the same temperature should have been found hitherto to be destructive to the simple and naked living matter entering into the composition of fungus-spores, and of bacteria and vibrios? If any other result had been ascertained, would there not have been much more reason for surprise?

We must therefore be very cautious how we attempt to set aside the conclusions which have been arrived at on this subject, based as they have been upon direct evidence of a most positive character, on account of other evidence which is indirect and more or less ambiguous. Concerning the legitimacy of such an attempt which has been made by M. Pasteur, I shall have more to say hereafter.

Passing on, then, to the more immediate consideration of our

* Etudes mycologiques sur les fermentations.
† Annales de Chimie et de Physique, 1862, p. 60.

subject, it should be distinctly understood that in all the discussions which have hitherto taken place on the possibility of the evolution of Living things, pre-existing *organic matter* has always been supposed to furnish the materials entering into the composition of the new organisms. New combinations and re-arrangements have been supposed to take place amongst the molecules of this pre-existing organic matter, under the agency of some mysterious force or forces—which new combinations of previously uncombined or differently combined molecules have been supposed to result in the production of such primordial living specks as monads and bacteria. The observations of preceding inquirers have also been conducted for the most part on infusions containing organic matter *in solution;* and since the molecules of such matter are then invisible, observers have, of course, been quite unable to follow, by any magnifying power at present attainable, variations in the modes of collocation of such invisible molecules. The minutest specks of living matter—the germs of monads and bacteria, and of the spores of fungi, less than $\frac{1}{50000}''$ in diameter—may be seen gradually appearing under the microscope in previously homogeneous solutions containing none of them.* But although microscopical investigation enables us to adduce evidence of just the same kind in elucidation of the mode of origin of certain low organisms, as we possess in explanation of the mode of origin of crystals,† this evidence is not deemed adequate in the case of organisms. A living thing has been supposed to be a something altogether different, incapable of arising out of a mere collocation of matter and of motion; and, therefore, under the influence of this theoretical assumption, whilst chemists and physicists have thought that they could in a measure account for the genesis of crystals by reference to the affinities and atomic polarities of the ultimate constituents of such crystals, they have, for the most part, declined to adopt a similar mode of reasoning in order to account for the appearance of the minutest living specks in solutions containing organic matter. The same reservation is likewise made by the major part of the biologists of the present day. Whilst it is not an article of faith—whilst such a surmise scarcely crosses our minds—that crystals always proceed from pre-existing germs, in the case of Living things, on the contrary, the doctrine *omne vivum ex vivo* has become almost one of the "forms of thought." Principally owing, therefore, to certain theoretical views concerning Life, and in order to account for facts which would otherwise be adverse to these, biologists and others have been accustomed to make the most extensive postulations concerning the supposed universal distribution of "germs" of all the lower kinds of living things; whilst they have recourse to no parallel hypothesis to account for the appearance of crystals, although we know no more—can drive our knowledge back no further into the phenomena attendant upon the birth of crystals than we can into the phenomena which usher in the appearance of organisms. In each case, under suitable conditions, they appear at first as minutest visible specks, in solutions which were previously homogeneous. In the one

* A more complete account of this part of the subject will be given in a work on *The Beginnings of Life*, shortly to be published.

† Or, better still, concerning the mode of origin of those modified crystals which appear on mixing solutions of gum and carbonate of potash, as described by Mr. Rainey (*On the Mode of Formation of the Shells of Animals, &c.*, 1858). The malate of lime contained in the gum is decomposed, but owing to the slow mixing of the solutions in the presence of gum, the insoluble carbonate of lime does not appear in its usual crystalline condition, but in globular modifications, resembling calculi. When portions of the two solutions are mixed under the microscope, Mr. Rainey thus describes what takes place:—"The appearance which is first visible is a faint nebulosity at the line of union of the two solutions, showing that the particles of carbonate of lime, when they first come into existence, are too minute to admit of being distinguished individually by the highest powers of the microscope. In a few hours exquisitely minute spherules, too small to allow of accurate measurement, can be seen in the nebulous part, a portion of which has disappeared, and is replaced by these spherical particles. Examined at a later period, dumb-bell-like bodies will have made their appearance, and with them elliptical particles of different degrees of excentricity" (p. 9). Mr. Rainey made use of one of Ross's ⅛" object glasses. These modified crystals are produced with no more rapidity than the lowest living things seem to be in other solutions, during hot weather; and the shapes of the products in the two cases are remarkably similar, judging from Mr. Rainey's figures. The protraction of the process, brought about by the presence of gum, serves to bring out more clearly the real relationship existing between the formation of crystals and that of the lowest organisms, in homogeneous solutions.

That there are very strong reasons accounting for this belief I do not attempt to deny. There is, however, much evidence to show that the very same organisms which do propagate their kind after this acknowledged method, may themselves originate *de novo.* Whilst allowing, therefore, the widest generality to any given rule, we may well hesitate before, on this account, we reject certain other alleged facts which are complementary rather than contradictory.

case we have to do with *crystallisable* matter, in solution, and in the other with those big-atomed, unstable compounds which constitute the so-called *colloidal* states of matter. And it is well to call attention to the fact that, concerning these latter states, the late Professor Graham, one of the most cautious and philosophical of chemists, wrote:*—"Another and eminently characteristic quality of Colloids is their mutability. Their existence is a continual metastasis. . . . . . The Colloidal is, in fact, a dynamical state of matter, the crystalloid being the statical condition. The colloid possesses ENERGIA. *It may be looked upon as the probable primary source of the force appearing in the phenomena of vitality.* To the gradual manner in which colloidal changes take place (for they always demand time as an element) may the characteristic protraction of chemico-organic changes also be referred."

Granting, then, that microscopical evidence alone may not be quite satisfactory for settling the mode of origin of such primordial living things as monads and bacteria, it becomes obvious that we must endeavour to throw light upon this evidence by other methods of investigation. Still it should also be kept steadily in mind that microscopical evidence is equally powerless to throw light upon those primordial collocations which initiate the formation of crystals. The problem concerning the primordial formation of crystals and living things is essentially similar in kind. Any difference in degree between our present knowledge on these two subjects must not blind us as to their essential similarity. Monads and bacteria are produced as constantly in solutions of colloidal matter as crystals are produced in solutions containing crystallisable matter. Crystallisable substances are definite in composition, and give rise to definite statical aggregations; whilst colloidal substances, much more complex and unstable, give rise on the contrary to dynamical aggregations. These dynamical aggregations, though they at first make their appearance in the form of monads and bacteria, are, by virtue of the properties of their constituent molecules, endowed with the potentiality of undergoing the most various changes, in accordance with the different sets of influences to which they are submitted. They are dynamical aggregates, in fact, in a condition of unstable equilibrium, and are capable of being diverted into new modes of current and reciprocal molecular activity in response to changes in their medium or environment. These differences between the products met with in solutions containing crystallisable and colloidal matter respectively, may, however, be due simply to the original difference in nature between such kinds of matter. Respecting the origin of the first visible forms which appear in either kind of solution, the evidence which we possess is precisely similar in nature. If such microscopical evidence does not enable us to get rid of the doubt that the smallest visible specks of living matter may have originated from *invisible* "germs" of such organisms, neither does it any more enable us to dispense with the supposition that the smallest visible crystals may have originated from pre-existing *invisible* "germs" of crystals. There is, in fact, so far as actual scientific evidence goes, almost as good reason for a belief in the universal distribution of invisible "germs" of crystals, as there is for our belief in the universal distribution of invisible "germs" of monads and bacteria. The very existence of the one set of invisible "germs" is, in fact, just as hypothetical as the existence of the other. Monads and bacteria we do know; but concerning the existence of invisible "germs" of monads and bacteria we know just as little as we do concerning the existence of invisible "germs" of crystals.

And yet almost all the difficulties in finally settling the question of the truth or falsity of the doctrines of "spontaneous generation" are centered in this question as to the mode of origin of monads, bacteria, and such fungus-spores as similarly originate in homogeneous solutions in the form of the most minute specks of living matter.† Given the existence of such primordial living particles, and we can easily watch changes taking place in aggregations of them, which lead to the production of much larger and altogether different organisms. We can then trace out with the microscope various kinds of evolution—processes of so-called "spontaneous generation," in fact—the establishment of the reality of which is just as much in opposition to generally received biological notions, as is the supposition that the primordial units themselves are able to come into being *de novo* after particular modes of collocation of colloidal molecules hitherto invisible. The amount of difference between such invisible organic molecule and the speck-like organism less than $\frac{1}{50000}$" in diameter, which appears in the previously homogeneous solution, may be no more real or striking than is the difference between some of the visible monads or bacteria and the much larger and higher kinds of living things, whose mode of origin I am about to describe, and which may be seen to arise after particular sets of changes have taken place in aggregations of such monads and bacteria. Of two things previously deemed alike improbable, the one which can come within the range of our vision may be shown to take place—the other being, unfortunately, beyond our ken, admits of no such proof. The unmistakeable upsetting of our preconceptions on the one subject should, however, make us cautious how, on theoretical grounds, we pronounce that to be impossible in the case of organisms which we, nevertheless, believe to be possible and actual in the case of crystals: especially when, in these two sets of cases, the amount of actual evidence which we possess is almost equal and similar.

Waiving, then, for the present the consideration of additional evidence as to the mode of origin of the primordial living particles, the monads and bacteria, and of the apparently similarly originating fungus-spores, I will describe some of the evolutional changes by which higher organisms may be seen to arise in a pellicle formed by an aggregation of the simpler kinds of living particles.

I.

The Mode of Origin of Unicellular Organisms and of Spores of Fungi in the "proligerous pellicle" of organic solutions.

What Burdach named the *proligerous pellicle* of organic solutions is made up of an aggregation of monads and bacteria in a transparent jelly-like stratum, on the surface of the fluid. It constitutes at first a thin scum-like layer, and although the monads and bacteria entering into its composition are motionless, M. Pouchet and others were not warranted in assuming from this fact alone that they were dead. There is, indeed, good reason for believing to the contrary, since, as pointed out by Cohn, when any of these particles are set free from the broken edge of a pellicle they always resume their movements. Motion, therefore, may simply be prevented by the presence of the transparent jelly-like material in which they are imbedded, although the particles may be undoubtedly living.

My observations on this subject have been principally carried on throughout the winter months; and this is a time not favourable for the appearance of ciliated Infusoria in organic infusions. Hence it is, perhaps, that I have not been able to witness any of those changes in the pellicle which have been described by Pouchet, as resulting in the evolution of *Paramœcia*, *Kolpodæ*, and other ciliated Infusoria. The changes which I have observed, however, have been so indubitable in nature, have been seen so frequently, and have had such a close general resemblance to those which have been described as leading to the evolution of *Paramœcia*, that I am quite disposed to believe in the correctness of the observations that have been made by Pouchet and others on this part of the subject.

My own observations have been conducted principally on the pellicle of hay infusions, and one of the commonest processes of what may be termed *secondary organisation* takes place in the following manner. In a pellicle which previously presented a uniform appearance, certain areas, altogether irregular in size and shape—though always presenting outlines bounded by curved lines—gradually make their appearance. These are, at first, distinguishable from the general ground-work of the pellicle only by their somewhat lighter aspect. On careful microscopical examination with high powers, it may be seen that the boundary of such an area—measuring it may be as much, or more than $\frac{1}{300}$" in diameter—is pretty sharply defined from the surrounding unaltered granular stratum. The immediately contiguous granules of this are occasionally somewhat more tightly packed, though at other times no such change is observable. In either case the unaltered portion of the pellicle is quite different from the included lighter area, because in this an increase has, apparently, taken place in the amount of jelly-like material between the granules, and, as well, there is a certain alteration in the refractive index, and occasionally in the size of the granules (monads and bacteria) themselves. The next change observable is, that the included area shows lines crossing it here and there, which at first tend to map it out into certain larger divisions. These intersecting lines gradually increase in number, till at last

* Philosophical Transactions, 1862. Capitals and italics are employed as we give them in the memoir itself.

† Such, for instance, is one of the modes of origin of *Torula* cells.

the mass becomes divided into an aggregation of rounded or ovoid bodies each about $\frac{1}{5000}''$ in diameter. As these subdivisions are taking place, the mass as a whole separates from the unaltered pellicle by which it is surrounded. Occasionally there is

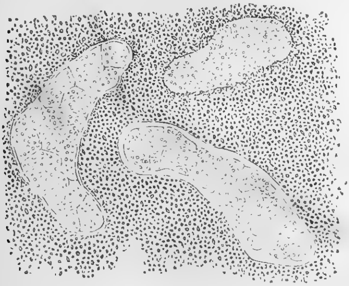


FIG. 1.—Development of Unicellular Organisms: three areas of differentiation showing different stages.

the most distinct interval, at a certain stage, between the parent pellicle and this differentiating mass, whose subdivisions also gradually separate from one another. These subdivisions now appear as independent unicellular organisms, bounded by a delicate membrane, and containing, perhaps, from four to eight of the altered monads and bacteria in their interior.

Throughout the winter months, such areas of differentiation and such resulting unicellular organisms were frequently met with. The unicellular organisms seem during such weather to persist for a very long time in this condition, merely, perhaps, increasing somewhat in size, and most of them ultimately become disintegrated without undergoing further development. They were always seen in a completely motionless condition, and presented no trace of a cilium, so that they were altogether different from the creature known as *Monas lens*. In one solution of hay in which such organisms had been present for some time, after a few days of warmer weather, several of them were found to have become spherical, and to have undergone a considerable increase in size. Some of these were as much as $\frac{1}{2000}''$ in diameter, and on one occasion a stage in the actual transition of one of these unicellular organisms into an *Amœba* was seen with the most perfect distinctness. One

FIG. 2.—Reţresenting gradual enlargement of Unicellular Organisms, and conversion of one of them into an *Amœba*.

half of the organism was distinctly amœboid in character, whilst t'ie other half was almost unchanged, containing large granules like those in the unaltered cells. As slow alteration in shape, of a slug-like character, took place in the anterior diaphanous protoplasmic portion, slow rolling movements occurred amongst the granules in the posterior cell-like portion, whose matrix seemed to have been rendered more fluid. I watched this organism for about half an hour, and then, wishing to examine other portions of the specimen of pellicle in which it had been contained, I moved the glass and was afterwards unable to find this particular specimen again. Unfortunately, I could discover no other Amœbæ or transition states.*

In other cases the areas of differentiation, commencing in a somewhat similar way, terminate in the production of spores of fungi, and I will now describe the mode of evolution of such s,ores as I observed it taking place in portions of a pellicle having a brownish colour, from an old infusion of hay. The development of this brownish tinge in the earlier stages made it more easy to unravel the nature of the earlier changes. The areas which began to differentiate were generally not very large. They were at first quite colourless, and the granules were separated from one another by a notable amount of transparent jelly-like material. The granules themselves were mostly shaped like the figure 8, and each half was about $\frac{1}{30000}''$ in diameter. A later stage was seen, apparently, in other areas which had assumed a very faint brownish tinge, and which presented evidences that

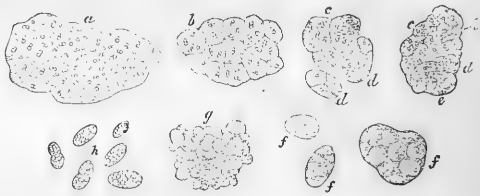

FIG 3.—Mo:le of origin of Spores of Fungi out of differentiating portions of a Pellicle formed on an infusion of hay.

subdivision was taking place. As the process of subdivision progressed, so the brown tinge became gradually deeper. Ovoid masses were frequently seen about $\frac{1}{2000}''$ or $\frac{1}{1000}''$ in diameter, of a decidedly brown colour, with from 8 to 12 or more ovoid subdivisions within the common envelope. As multiplication advanced, the individual products lost all trace of their original granular condition. They became quite homogeneous and highly refractive masses of a brown colour, looking almost like large brown fat globules. At last, multiplication still proceeding, the distended, and always thin, cyst-like, general envelope becomes ruptured and disappears, leaving only an irregular mass of spherical or ovoidal bodies of various sizes. The individual segments, as soon as this process of multiplication has ceased, increase in size, and then gradually become less refractive and lighter in colour. A slight differentiation of their contents also again takes place, marked by the appearance of faint lines within, as they assume the appearance of ovoid bodies about $\frac{1}{4000}''$ in diameter.* Even when they have attained this stage of development, they may again undergo a process of division; though generally, after a time, they give origin to ordinary mycelial filaments.

Similar changes in the refractive index have been frequently noticed in other cases when a protoplasmic mass is at the same time differentiating and undergoing a process of multiplication,† whilst the mode and frequency of the sub-division is exactly comparable with what so frequently happens to the gonidia of lichens.

The changes which I have described represent, I think, only two extreme types of a mode of metamorphosis which is apt to take place in portions of the pellicle. In the one case a certain area of the pellicle, after undergoing some changes, resolves itself into a number of ovoid bodies, which collectively are about equal in bulk to the altered area itself; whilst, in the other case, at different stages, the segments of the altered area undergo a process of growth and sub-division, so that ultimately the mass of spores which results far exceeds in bulk that of the original area when it began to undergo change.

At other times, intermediate processes are met with, and then fungus-spores are produced after a fashion more closely resembling that which leads to the production of the unicellular organisms above described. The areas of change are then larger than those last described, and colourless throughout, whilst the processes of growth and multiplication are less marked at the different stages. Where fungus-spores result after this fashion, the changes in the refractive index, and the homogeneous appearance previously alluded to, still generally manifest themselves at the ultimate stage of division, though nothing of this kind shows itself in the more simple process leading to the production of the unicellular organisms.

Now, however mysterious the nature of these changes may be, which take place, as it seems to us, "spontaneously" in the pellicle on the surface of a solution of organic matter, they are exactly comparable with other changes occurring within the terminal dissepiments of a kind of submerged mucor, named *Achlya prolifera*, similar to those which occur within the thecæ of certain other fungi and of certain lichens, and altogether analogous to that which, as Prof. Haeckel says, takes place in

* Prof. Hartig has, however, described a similar mode of origin of Amœbæ from unicellular organisms, in his observations on the phytozoa of *Marchantiæ*. See *Journal of the Microscopical Society*, 1855, p. 51.

* The markings of these spores are more obscure and less regular than they are represented (*h*) in the woodcut.

† See Nicolet, in Thompson's *Arcana Naturæ*, 1859.

some of the simplest *Amœbæ*, after they have encysted themselves. In all these cases, formless and apparently homogeneous or merely granular living matter, resolves itself more or less rapidly into a number of individualised segments, which are

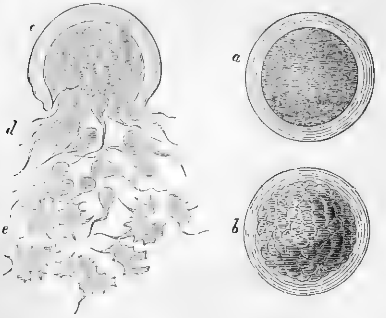

FIG. 4.—Representing subdivision of formless living matter within encysted *Protomyxa*, and exit of products from cyst as active tailed Zoospores, ch subsequently become converted into reptant Amœbæ (Haeckel).

capable of existing as independent living things.* These changes occur in the formless matter of definite organisms, and the products of subdivision tend to reproduce organisms of a similar kind; but the changes which take place in portions of the pellicle are changes occurring in fortuitously aggregated living matter, and the resulting products are, as might have been expected, more variable in kind. There is every reason to believe that the changes which take place in the homogeneous living matter of the encysted *Protomyxa* occur by reason of the molecular properties of this living matter, and are not occasioned by any occult influence exercised by the mere inert cyst-wall, which is but a product of the living matter that it

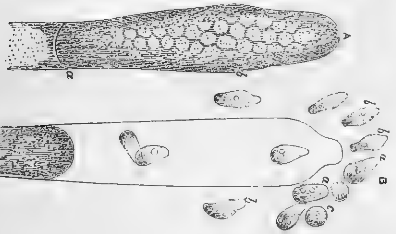

FIG. 5.—Showing the mode of origin of motile Zoospores within the terminal dissepiment of *Achlya* (Tulasne).

encloses. And so we have good reason for supposing that the changes which take place in the mere granular mucilage of the rapidly-formed terminal segment of an *Achlya*, by which this in the space of less than two hours resolves itself into free-swimming zoospores, is to be ascribed to the molecular properties of the mucilage itself which undergoes the change. In the pellicle, on the other hand, we have an aggregation of granular living matter also, and the observations which I have adduced simply go to show that those molecular properties of living matter which lead to its differentiation and further organisation, are not limited to the living matter that is contained within organisms of a definite type. Just as the changes which take place in the structureless living matter of these organisms seem to be due to the forces acting upon, and to the reactions amongst, the several molecules of which it is composed, so do the changes which occur in given areas of the pellicle seem referrible to the influence of physical forces upon the living molecules of which it is composed, and upon the mutual inter-action of these upon one another when under the influence of such incidence. In both cases the changes take place in living matter; in both cases they are the results of molecular activity: in the one set of cases they take place in a fortuitous aggregation of living matter, and the products are accordingly very variable in nature, whilst, in the other set of cases, just as they take place in living matter which constitutes part of a definite organism, so are the products more definite in kind.

But this process, which most certainly occurs in the living matter of a pellicle, is of a kind not hitherto generally recognised as one of the modes by which unicellular organisms, or spores of fungi, may originate. These are, in fact, instances of what has been called "spontaneous generation," or what we may better term heterogenous evolution. The majority of biologists would be as much inclined to believe that these processes did not take place as they are inclined to disbelieve that a monad or a bacterium may be born *de novo* in a solution of organic matter. The occurrence of the one process has been thought to be about as improbable as that of the other. Yet the one can be seen undoubtedly taking place with the aid of the microscope alone. Unfortunately, however, the organic molecules, which are supposed to coalesce in the solution of organic matter, in order to form the smallest visible Living particle, are themselves invisible. We cannot, therefore, trace the genesis of one of these particles with the aid of the microscope, any more than we are able to trace the genesis of a crystal beyond its *minimum visible* stage. In the one case physicists and biologists willingly assume that such ultimately visible particles are the products of a "spontaneous" coalescence of molecules, which are themselves invisible, whilst in the case of organisms they will grant no such assumption. They require us to prove, in fact, that such organisms have not been produced from pre-existing though perhaps invisible "germs," before they will grant for organisms that probability which they at once concede in the case of crystals. This difference which is made between the two cases seems due, in great part, to some theoretical views which are held concerning the nature of Life. And yet it would not be difficult to show that the metaphysical or vitalistic theories in question, to which they commit themselves, are directly opposed to some of the most accredited scientific doctrines of the day.* The doctrine of the Conservation of Energy and of the Correlation existing between the Vital and the Physical forces do, if pushed to their ultimate issues, inevitably bring us to the conclusion that the forces acting within all Living bodies are molecular forces, and that such forces are derived from the physical forces of the outside world just as surely as the matter of the organism formerly existed outside itself. The most careful interpretation of scientific evidence, moreover, would lead us to the conclusion that what is called the Life—or in other words the aggregate set of phenomena displayed by one of the simplest bodies which we call a living thing—is as much the essential and inseparable attribute of the particular molecular collocation which displays it, as the properties of the crystal are essential to the kinds and modes of aggregation of the molecules which enter into its composition. It may be maintained, therefore, that all *à priori* presumptions, based upon the best scientific evidence, would lead us to disbelieve the "vitalistic" theories which are still held by many at the present day. It is the vitalist, however, who alone has any logical reason for insisting that what may be a good and valid mode of accounting for the origin of crystals cannot be considered to hold good in the case of organisms. Those who believe that the forces acting in Living things manifest themselves in the individual molecules of which these are composed, and that such forces are convertible with the ordinary physical forces, have, on the other hand, strong *à priori* reasons for believing that Life will manifest itself wherever particular collocations of complex organic molecules occur. It rests, then, in reality, with the vitalist, who assumes the truth of a mere theory, in favour of which he can adduce no scientific evidence, to show why a different rule should be presumed to

* All this part of the subject will be much more fully treated in the work on *The Beginnings of Life*. The possession or not of the property of motility seems to be an altogether unessential characteristic. The products of subdivision of such an encysted *Amœba* as *Protomyxa aurantiaca* are motile zoospores, and so are those of the fungoid *Achlya prolifera*; but the reproductive products arising from the subdivision of the formless matter within the spore-cases of *Pezizæ* and other fungi are motionless, and this is the case also with the gonidia of the *Saprolegniæ*, which are fungoid organisms, otherwise almost undistinguishable from *Achlya*.

* This I shall attempt to show fully elsewhere.

hold good in the birth of crystals and of organisms respectively.* Those who hold opposite opinions need only suppose that molecules of "organic" matter, or some such complex molecules, may aggregate and arrange themselves after certain modes to produce a Living thing—just as a crystal, endowed with its particular properties, is producible by other modes of aggregation —because with them Life is considered to be a product of molecular collocation and of molecular change. And if the "vitalist" wishes to establish the existence of a more fundamental difference between crystals and organisms than we are prepared to grant, seeing that the scientific evidence seems to be against him, it remains for him at least to endeavour to show good grounds for the establishment of such difference.

It should be remembered, then, that in the present state of science all theoretical considerations seem favourable to the views of the evolutionists, and that the only thing which can be opposed to them is the *assumption* that those processes of reproduction which take place amongst all known varieties of living things are the *only* processes by which such living things can arise. But now, already, by means of microscopical evidence alone, it has been shown that Living things may arise by a process of heterogenesis—not as products of a pre-existing organism like themselves, but by a process altogether different from those which have been hitherto supposed to be general. And it is worth remembering, as we have before pointed out, that the supposed coalescence of invisible molecules and the changes which lead to the production of the minutest living monad in organic solutions, if they could be shown to be true, would not be one whit more startling than those very changes which, before disbelieved in, can now be easily shown to take place in the "proligerous pellicle." Have we not seen that out of a mere fortuitous aggregation of living particles, and the subsequent metamorphoses taking place therein, organisms appear which are much larger, and of a much higher type than those which preceded them, although such a mode of origin was formerly regarded almost as "impossible"?

* I will here make two quotations in order to show that the opinions of two of our leading scientific men (many others might have been quoted) are not at all opposed to the comparisons I have been instituting. They both, in fact, declare emphatically that the phenomena of Life are phenomena of molecular physics.

In his address to the Mathematical and Physical Section of the British Association in 1868, Prof. Tyndall, as president, speaking of a grain of corn, said:—"But what has built together the molecules of the corn? I have already said, concerning crystalline architecture, that you may, if you please, consider the atoms and molecules to be placed in position by a power external to themselves. The same hypothesis is open to you now. But if in the case of crystals you have rejected this notion of an external architect, I think you are bound to reject it now, and to conclude that the molecules of the corn are self-posited by the forces with which they act upon each other. It would be poor philosophy to invoke an external agent in the one case and to reject it in the other. . . . . But I must go still further, and affirm that in the eye of science the animal body is just as much the product of molecular force as the stalk and ear of corn, or as the crystal of salt or of sugar. . . Every particle that enters into the composition of a muscle, a nerve, or a bone, has been placed in its position by molecular force. And unless the existence of law in these matters be denied, and the element of caprice introduced, we must conclude that, given the relation of any molecule of the body to its environment, its position in the body might be predicted. Our difficulty is not with the *quality* of the problem, but with its *complexity*." (Pp. 4 and 5.)

Prof. Huxley, again, in his article on "Protoplasm," in the *Fortnightly Review* for February 1869, says:—"Carbon, hydrogen, oxygen, and nitrogen are all lifeless bodies. Of these, carbon and oxygen unite in certain proportions and under certain conditions to give rise to carbonic acid; hydrogen and oxygen produce water; nitrogen and hydrogen give rise to ammonia. These new compounds, like the elementary bodies of which they are composed, are lifeless. But when they are brought together under certain conditions they give rise to the still more complex body, protoplasm; and this protoplasm exhibits the phenomena of life. I see no break in this series of steps in molecular complication, and I am unable to understand why the language which is applicable to any one term of the series may not be used to any of the others. We think fit to call different kinds of matter carbon, oxygen, hydrogen, and nitrogen, and to speak of the various powers and activities of these substances as the properties of the matter of which they are composed. . . . Is the case in any way changed when carbonic acid, water, and ammonia disappear, and in their place, *under the influence of pre-existing protoplasm*, an equivalent weight of the matter of life makes its appearance? . . . What justification is there, then, for the assumption of the existence in the living matter of a something which has no representative or correlative in the not living matter which gave rise to it?" (The passage I have marked by italics indicates the extent to which Prof. Huxley stops short of the views I have been endeavouring to support.)

Now I maintain that the logical outcome of such doctrines as these is that Life *may* manifest itself whenever certain particular collocations of complex molecules occur, just as surely as crystalline properties will be manifested by chloride of sodium whenever the molecules of this substance combine to form crystals. The *à priori* presumptions being rather in favour of (certainly not opposed to) the occurrence of the new evolution of Living things, we have to show, as well as we are able, that there *is* a tendency to the occurrence of such clusterings as will lead to the formation of bacteria or of fungus-spores, just as we feel compelled to believe that there is a tendency to the occurrence of those particular clusterings of molecules which result in the formation of crystals.

II.

On the probable Evolution of Living Things in Organic and Saline Solutions, which have been previously exposed to high Temperatures, in airless and hermetically sealed vessels.

We must now come to the consideration of all the experimental evidence which can be adduced in support of what the microscope teaches us as to the mode of origin of the lower kinds of Living things.

The method of experimentation which has been principally relied upon, has, since 1837, always been that introduced by Schwann. Sometimes the correspondence has been exact, and sometimes his experiments have been repeated with some slight modification. In this method, the solution of organic matter is first boiled in a flask, the neck of which is securely connected with a tube closely packed with portions of red-hot pumice-stone, or other incombustible substance: after the solution has been boiled for some time, and all the air of the flask has been expelled, the flask itself is allowed to cool whilst the tube containing the closely-packed red-hot materials is still maintained at the same temperature, in order that whatever air enters into the flask may be subjected to a calcining heat as it passes through the tube. When the flask has become cool it will then contain only the previously boiled solution in contact with air at ordinary atmospheric pressure, which has been calcined. Since it has been hitherto settled that the lower kinds of organisms which may be contained in the solutions, are destroyed when these fluids are raised to a temperature of 100° C., and that no organisms have been known to survive after having remained for thirty minutes in air raised to a temperature of 130° C., the boiling of the fluid for a time and the calcination of the air has generally been supposed to be a sufficient precaution to ensure the destruction of all organisms in the experimental media. Experiments conducted in this way have been said to yield negative results by some, whilst others have maintained that in spite of all such precautions, destined to destroy pre-existing Living things, they do, nevertheless, obtain low kinds of organisms, after two or three months, if not before, in their experimental fluids.

Negative results in these experiments can of course prove little or nothing; they may be explained equally well by either party: either no organisms have been found, because they or all the germs which could give rise to them have been killed; or it is just as fair for the evolutionists to explain the absence of organisms on the supposition that the particular fluids employed have not yielded them because of the severity of the destructive conditions to which the particular organic matter in the previously boiled fluids had been subjected. When organisms *are* found, however, in fluids which have been legitimately subjected to the conditions involved in Schwann's experiments, then one of two things is proven: either the amount of heat which hitherto was deemed adequate to destroy all pre-existing organisms is in reality not sufficient, or else the organisms found must have been evolved *de novo* as the evolutionists suppose. Unless, therefore, the standard of vital resistance to heat can be shown to be higher than it was formerly supposed to be, any single positive result when Schwann's experiment has been legitimately performed, is of far more importance towards the settlement of the question in dispute than five hundred negative results. It would tend to show that in the particular fluid employed organisms might be evolved *de novo*. And yet positive results in the performance of these experiments have been obtained again and again by Schwann himself, by Ingenhousz, by Mantegazza, Pouchet, MM. Joly, and Musset, Jeffries Wyman, Dr. Child, and, not to mention any others, even by M. Pasteur himself.*

But even this is not all; organisms have been found in fluids which had been contained in closed vessels, after exposure to conditions still more severe. Prof. Jeffries Wyman, of Cambridge, U.S., published an account (which I am sorry to say I have been unable to obtain from any of our libraries) in 1862 of experiments in which he had boiled fluids containing organic matter for a period of two hours under a pressure of two atmospheres, that

* We have the testimony of M. Pasteur to the fact that organisms may almost always be met with when milk or some other alkaline fluid is made use of in Schwann's experiment. He says he has always met with negative results, however, if such fluids have been raised to a temperature of 110° C. rather than 100° C. Concerning his inferences from these experiments I shall have more to say hereafter.

is to say, at a temperature of 120·6° C. To the fluids so treated no air was allowed access, except what had passed through the capillary bores of white-hot iron tubes. And yet, when the flasks were broken, after a certain time, organisms were found in the fluids which had been submitted to these conditions. Prof. Mantegazza has obtained organisms from the fluids of hermetically closed flasks, after these, containing the putrescible fluids and common air at ordinary atmospheric pressure, had been subjected for some time to a temperature of 140° C.; and Prof. Cantoni, of Pavia, has obtained bacteria and vibrios in the fluids of similarly prepared closed flasks, after these had been exposed in a Papin's digester to a temperature of 142° C. for four hours. And still, though no positive evidence has been forthcoming to show that the standard of vital resistance can be raised—though nobody has shown that any Living thing which has been made the subject of experimentation has been found alive after an exposure for a minute or two in a fluid raised to 100° C., or after an exposure for thirty minutes to a temperature of 130° C. in dry air or *in vacuo*, many scientific men are as much disinclined as ever to admit that the organisms found by the above-mentioned observers could have been evolved *de novo*.

For all those, however, who form their opinions on such matters in accordance with scientific evidence, rather than in obedience to theoretical preconceptions, it must be admitted that the balance of evidence is at present altogether in favour of the supposition that organisms can arise *de novo*. And it only remains for those who are opposed to the notion from an *à priori* point of view to bring forward positive evidence tending to show that the standard of vital resistance, for the organisms in question, is much higher than it has been hitherto shown to be.

Some of the additional evidence I have now to bring forward, therefore, only tends to strengthen the validity of the conclusion which was already deducible from the experiments of Pouchet, Wymann, Mantegazza, Cantoni, and others.

Hitherto, in speaking of the experiments of Schwann, I have only incidentally referred to the destructive influence of heat upon the organic matter contained in the solutions, though very strong evidence could be adduced to show that such organic matter is notably altered after these solutions have been raised to the temperature of 100° C. The disruptive agency of heat is fairly enough supposed by the evolutionists to destroy some of the more mobile combinations in each solution—to break up, more or less completely, in fact, those very complex organic products, whose molecular instability is looked upon as one of the conditions essential to the evolutional changes which are supposed to take place. I shall postpone for the present the consideration of the question as to how far this destructive agency of heat is affected by the alkalinity, neutrality, or acidity of the fluids, though I shall towards the close of this paper bring forward evidence tending to show that organic matter in acid solutions is more damaged by the temperature of 100° C. than is that which is contained in neutral or slightly akaline solutions, when these are heated to the same extent.

To any one looking boldly at the problem, the question which now seems to suggest itself is, whether any other substances can be employed in place of the organic matter, such as would not be injured by a temperature of 100° C., and which, whilst containing the necessary elements for the formation of an organism, might also permit the occurrence of those peculiar molecular re-arrangements which result in the formation of Living things? Postponing, however, the consideration of this question for the present, I will first refer to the influence of another of the detrimental conditions involved in Schwann's experiments.

In those instances where the results were positive, and in which calcined air and previously heated organic solutions were shut up in hermetically-sealed vessels, nothing but the lowest forms of living things ever appeared—mere monads, bacteria, and vibrios—and these generally not till after the expiration of two, three, or more months. There seems reason to believe that the delay, and the very low forms of the organisms met with, are attributable, in great part, to the increased tension which almost invariably occurs within the closed vessels. In some cases the tension becomes so great that it ultimately bursts the flasks. This took place several times in the course of Dr. Child's experiments. After reflection upon these facts, it seemed to me that there was not much room for surprise, looking at it from the evolutionist's point of view, that the results should have been so unsatisfactory. The small amount of space above the level of the fluid, is already occupied, at the time that the flask is hermetically sealed, with air under ordinary atmospheric pressure. But, when putrefactive or evolutional changes begin to take place in the fluids containing organic matter, such changes are almost sure to be attended by the liberation of gases either simple or compound. And in direct proportion to the extent of the liberation, so does the tension and consequent pressure upon the fluid increase within the flask. This pressure upon the solutions might and probably would tend to prevent, in proportion to its extent, those life-giving re-arrangements which are presumed to take place amongst the molecules of the organic matter contained therein. Having come to this conclusion, and as there also seemed to be good reason for the belief that atmospheric air was not needed for the development of bacteria and vibrios, it occurred to me that it would be possible so to modify the experiment of Schwann that it might be repeated under conditions more satisfactory to the evolutionists, and at the same time in a way which would be not less in accordance with the views of the panspermatists. The withdrawal of all air from the flasks in which the boiled solutions were contained, rather than the admission of calcined air, seemed to be the kind of modification which was desirable.* Then the contamination of the boiled fluids with possible atmospheric germs would be as effectually provided against as if air had been only allowed to enter after it had been calcined, and the seemingly obvious advantage would be attained that there would be even greater freedom than usual for the commencement of evolutional changes, on account of the diminished pressure upon the fluids contained *in vacuo*. It was presumed, also, that changes might go on for a certain extent before the evolution of gases had been sufficient to exercise such a repressive influence as to prevent their continuance.

The results of experiments conducted upon these principles have been most uniform, and have been of such a nature as to tend to support the truth of the reasonings which dictated them.

The flasks employed have generally been of small size, capable of holding about two ounces of fluid. These have proved to be quite large enough, and their small size made it easy for me to manage the whole process with a very slight amount of assistance. The method adopted was as follows:—After each flask had been thoroughly cleaned with boiling water, three-fourths of it was filled with the fluid which was to be made the subject of experiment. With the aid of a small hand blow-pipe and the spirit-lamp flame, the neck of the flask, about three inches from its bulb, was then drawn out till it was less than a line in diameter. Having been cut across in this situation, the fluid within the flask was boiled continuously for a period of from ten to twenty minutes. At first ebullition was allowed to take place rapidly (till some of the fluid itself frothed over) so as to procure the more thorough expulsion of the air; then the boiling was maintained for a time at medium violence over the flame of my reading-lamp, whilst the greatly attenuated neck of the flask was heated in the flame of a spirit-lamp placed at a corresponding level. The steam for a time poured out violently into the flame of the spirit-lamp; and whilst my assistant (my wife) turned down the flame of the reading-lamp so as to diminish still further the violence of the ebullition, I directed the blow-pipe flame upon the narrow orifice of the neck of the flask, and so sealed it hermetically. Immediately that the orifice was closed, the heat was withdrawn from the body of the flask.

After a little practice I soon became able to procure in this way an almost perfect vacuum. Even though the vessels were

* I was actually led to adopt this important modification, perhaps, by a mere chance. In the spring of last year Mr. Temple Orme, of University College, had kindly undertaken to perform some experiments with me bearing upon the subject of "Spontaneous Generation." We at first proposed to repeat, with some very desirable variations which he suggested, Schultze's experiments. One day, however, he told me he had boiled an infusion of hay for four hours, and had then hermetically sealed the neck of the flask whilst ebullition continued. In this way a more or less perfect vacuum was procured. This he did as a sort of tentative experiment, and it was then, on thinking over the subject, that I resolved to give the plan a thorough trial, as it appeared to me that by so doing I should be working under conditions which were most in accordance with the theory of evolution. I performed four experiments at that time in concert with Mr. Temple Orme, with hay infusions which had been boiled for four hours and had then been sealed up *in vacuo*. In each of these fluids organisms were found after a comparatively short time. These were the first experiments performed under such conditions. In my subsequent work I have not had the benefit of Mr. Orme's personal assistance, although I have frequently profited by suggestions which he has made.

so small, momentary ebullition could generally be renewed again and again for the space of five minutes after they had been hermetically sealed, by the mere application of one of my fingers, which had been dipped into cold water, to a portion of the glass above the level of the fluid. The water-hammer effect was also very obvious in several which were tested in this fashion.

I believe that an almost perfect vacuum can be produced in this way; in the first violent ebullition the air is driven out of the flask by the fluid, and as ebullition is continuously kept up after this till the flask is hermetically sealed, there is always an outpouring of heated vapour, and no opportunity for a re-ingress of air. But, even if in any given case the vacuum should not prove to be absolute, it does not seem to me that there would be any material abatement from the severity of the conditions which the panspermatists have a right to demand. If, on the one hand, absolutely the whole of the air had not been expelled from the flasks during the process of ebullition, what remained would necessarily be mixed up with a very much larger quantity of continually renewed aqueous vapour, and the effect would probably be that any living things would be just as effectually and destructively heated as if they were lodged in the boiling solution itself; whilst if, on the other hand, the boiling had been arrested for one or two seconds before the complete closure of the almost capillary orifice at the mouth of the flask, even if any air entered, it would have had first to pass through the blow-pipe flame, and then through the white-hot capillary orifice—it would in fact have been calcined as in Schwann's experiment. The conditions of the experiment would then have been no less severe, and the only effect would be that the vacuum with which I prefer to work would have been rendered by so much the less complete. Although I make these remarks with the view of meeting criticisms, I am inclined to think that the vacuum in my experiments has been complete; and it should be remembered that M. Pasteur always adopted this method when he wished to preserve solutions for a time *in vacuo*. Whenever he desired to make comparative trials with the air of different localities, the solutions which had been prepared in this way were assumed by him to be contained *in vacuo*, so that the flasks could then be taken to the localities, with the air of which he wished to experiment. There the necks of the flasks were broken, in order that they might become filled with the air of the respective localities. After this had been done the flasks were resealed, and kept for future observation of their contained fluids. M. Pasteur, M. Pouchet, and others who adopted this method, carried away their experimental fluids *in vacuo*, during a two or three days' journey to the Alps or to the Pyrenees, and it never seemed to have occurred to either of them that evolutional changes might be taking place during their journey. M. Pasteur, in fact, habitually shut his eyes to all such possibilities, they did not come within the range of what he considered possible; such thoughts might, however, have suggested themselves to M. Pouchet and others, although this does not seem to have been the case.

After the flasks had been prepared in the way above mentioned, they were suspended beneath the mantelpiece in my study. During the day there was always a fire in the room, and at night I put my reading lamp underneath them with the flame properly turned down. So far as I have been able to ascertain, the temperature to which they have been subjected has mostly ranged between 23°—29° C. (75°—86° F.) Sometimes they have been exposed to the lower temperature and sometimes to the higher, and I suspect that a variation of this kind may perhaps be more favourable for the production of evolutional changes than maintenance at a constant temperature.

In detailing the results of the following experiments, I shall not enter into any minute description of the organisms found. My main object throughout has been to obtain evidence on the subject as to whether a *de novo* evolution of Living things could or could not take place. The demands upon my time have been so serious in the carrying on of these investigations, that occasionally it has only been small portions of the experimental fluids which have been examined. If, for instance, what I found in the first few drops of the fluid left no doubt in my mind as to the nature and abundance of some Living things contained therein, the remaining portions of the fluid were frequently not examined. Other bodies, therefore, may have been contained in the solutions, which were never seen at all.

H. CHARLTON BASTIAN

(*To be continued.*)

SCIENTIFIC SERIALS

THE *American Naturalist* for June contains several excellent articles. The first is by Prof. J. S. Newberry, "On the Surface Geology of the Basin of the great Lakes and the Valley of the Mississippi." In the northern half of this area down to the parallel of 38° to 40° N. lat., are found, not everywhere, but in most localities where the nature of the underlying rocks is such as to retain inscriptions made upon them, the unmistakeable indications of glacial action. Some of the valleys and channels which bear the marks of glacial action, evidently formed or modified by ice, and dating from the ice period of an earlier epoch, are excavated far below the present lakes and water-courses which occupy them. These valleys form a connected system of drainage at a lower level than the present river system, and lower than could be produced without a continental elevation of several hundred feet. Upon the glacial surface are found a series of unconsolidated materials, generally stratified, called the drift deposits. These consist in the lowest stratum of the Erie clays of Sir William Logan, above which are sands containing beds of gravel; and near the surface elephants' teeth have been found, water-worn and rounded. Upon these stratified clays, sands, and gravel of the drift, are scattered boulders and blocks of all sizes, of granite, greenstone, siliceous and mica slates, and various other metamorphic and eruptive rocks, generally traceable to some locality in the Eozoic area of the lakes. Among these boulders many balls of native copper have been found, which could have come from nowhere else than the copper district of Lake Superior. Above all these drift deposits, and more recent than any of them, are the "lake ridges," corresponding to our raised sea-beaches, embankments of sand, gravel, sticks, leaves, &c., which run imperfectly parallel with the present outlines of the lake margins, where highlands lie in the rear of such margins. The general conclusions drawn are the existence of a glacial epoch over the northern half of the continent of North America, probably contemporaneous with that of Europe, and with a climate comparable to that of Greenland; that the courses of these ancient glaciers correspond in a general way with the present channels of drainage; and that at this period the continent must have been several hundred feet higher than now.—"A Winter's Day in the Yukon Territory," by W. H. Dall, refutes the prevalent idea, perpetuated even by "official" reports, that the island of St. Paul is surrounded in winter by immense masses of ice, on which the polar bears and arctic foxes sail down from the north and engage in pitched battles with the wretched inhabitants. The fact is that there is no solid and very little floating ice near St. Paul in winter; the arctic foxes found there as well as on most of the islands were purposely introduced by the Russians for propagation, a certain number of skins being taken annually; and there is no authentic evidence that the polar bear has ever been found south of Behring's Straits. The country of Alaska comprises two climatic regions, which differ as widely as Labrador and South Carolina in their winter temperature. One contains the mainland north of the peninsula of Alaska and the islands north of the St. Matthew group; the other includes the coast and islands south and east of Kadiak, while the Aleutian Islands, with the group of St. Paul and St. George, are somewhat intermediate. A day's excursion during the winter season in the northern and more inhospitable of these two regions yielded a considerable number of interesting animals.—Articles of a popular character are "Our native Trees and Shrubs," by Rev. J. W. Chickering, Jun.; and "A Few Words about Moths," by A. S. Packard, Jun. A review of Principal Dawson's article in the *Canadian Naturalist* on "Modern Ideas of Derivation," criticises, favourably on the whole, that writer's strictures on the Darwinian theory of Natural Selection.—The Natural History Miscellany contains many interesting notes, either original or culled from English scientific journals.

The fourth part of the *Jenaische Zeitschrift für Medicin und Naturwissenschaft*, June 1870, contains the following important articles. 1. Gegenbauer on the skeleton of the limbs of Vertebrata, and of the Selachia and Chimæra in particular. 2. Abbe on a spectrum apparatus for the microscope. 3. Dr. Dohrn: Further researches on the structure and development of the Arthropoda, especially bearing on the Zoea stage of Crustacea; and lastly, a long and interesting paper by Ernst Haeckel on the "Plastiden-theorie," in which he treats fully of the deep-sea life brought to light by the dredgings of Drs. Wallich, Carpenter, Wyville Thomson, Huxley, and others, describing the Bathybius, Coccoliths, Globigerina, &c. He confesses himself unable to solve the problem of the origin of the immense quantities of protoplasm that form a bottom to the sea, but is disinclined to regard it as consisting of the mycelium of sponges, an opinion advanced by Wyville Thomson. He finds the well-known yellow cells of Radiolaria to contain starch, the reactions of which are not distinguishable from those characteristic of starch derived from vegetables. These starch granules make up more than half of the entire mass of the Radiolaria.

The *Bulletin de la Société Imperiale des Naturalistes de Moscow*, 1869, No. 2 (received June 15, 1870), contains, amongst other valuable papers, a carefully-worked-up description of the anatomy and development of the *Pedicellina*, by B. Uljanin, which is accompanied by two plates illustrating the changes undergone as far as he had an opportunity of observing them.

In the last number (Heft iv. Band lx.) of the *Sitzungsberichte der K. Akad. der Wissenchaften zu Wien* is a long paper by Dr. A. Polotebnow on the origin and mode of increase of Bacteria. These, as most of our readers are aware, consist of very small rods, which present a kind of tranverse striation at tolerably regular intervals, like an extremely diminutive sugar-cane of from two to six or seven joints, and which exhibit irregular vibratory movements. They have been, like other lowly organised forms, sometimes considered, as by Dujardin, to belong to the animal kingdom; sometimes, as by Cohn, to represent a form of vegetable life; and sometimes, as by Pertz, to occupy an intermediate position on the confines of the two kingdoms. Dr. Polotebnow finds that an unbroken series of forms can be observed between the minute round cells which form the mycelium of *Penicillium*, and probably other fungi, and fully-developed Bacteria. In regard to their multiplication, he thinks this can only occur from the cells above mentioned, and that when they have once become fully formed Bacteria they are no longer capable of further multiplication.

SOCIETIES AND ACADEMIES

London

Geological Society, June 8.—Mr. Joseph Prestwich, F.R.S. president, in the chair.

Mr. Henry G. Vennor, of the Geological Survey of Canada, Montreal; Alexander Kendall Mackinnon, Memb. Inst. C. E., Director-General of Public Works, Montevideo, South America; and Mr. Arthur Roope Hunt, Quintella, Torquay, were elected Fellows of the Society.

1. "On the Superficial Deposits of the South of Hampshire, and the Isle of Wight." By Thomas Codrington, F.G.S. This paper treated of the gravel deposits covering the tertiary strata of the country between Portsmouth and Poole, and of the Isle of Wight. The strikingly tabular character of the surface is best seen on the east of the Avon, where from the coast for more than twenty miles inland a gravel-covered plain can be followed, rising gradually from 80 feet to 420 feet above the sea, at the rate of about 20 feet per mile. The high plains of the New Forest, to the eye perfectly level, and indented by deep valleys, are portions of this table-land. The plateau between the Bournemouth Cliffs and the Valley of the Stour, and detached gravel-capped hills further inland, are the remnants of a similar table-land on the west of the Avon, while eastwards the same character prevails up to Southampton Water. Sections parallel with the coast show the level nature of the country, broken only by well-defined river-valleys. On the east of Southampton water a similar tabular surface, sloping at a steeper angle towards the shore-line, and cut through by the valleys of the Itchen, Hamble, and Titchfield rivers, remains; and in the Isle of Wight the gravels capping the flat-topped tertiary hills coincide with a corresponding plain sloping northwards. The gravel covering these table-lands is composed chiefly of subangular chalk-flints, with a varying proportion of tertiary pebbles. Sarsen stone blocks are found everywhere, and on Poole Heath granitic pebbles; and in the gravel of Portsea large boulders of granitic and palæozoic rocks are met with. In the Isle of Wight, chert from the Upper Greensand, and materials from the Lower Cretaceous beds also occur. The colour of the gravel is generally red; and the origin of the white gravel, which often overlies the red, is to be ascribed to the bleaching action of vegetable matter. Brick-earth is generally associated with the gravel at all levels but the highest; but the contorted appearances attributed to glacial action only occur at low levels. No organic remains have been found in the gravel covering the plains, while the valley-gravels of the district have afforded mammalian bones and teeth of the usual species. Flint implements have been found at Bournemouth at 120 feet above the sea; at Lymington, near Southampton, at 80 and 150 feet; and also along the shore between Southampton Water and Gosport, at 35 feet above the sea, from gravel forming part of the covering of the tabular surface, and unconnected with the river valleys. The gravel capping the cliffs of the south coast of the Isle of Wight, in which the remains of *Elephas primigenius* have been found near Brook and Grange, was probably deposited in the same river-basin as the mammaliferous gravel of Freshwater; and the cutting back of the coast-line by the sea has given the tributaries of a river which flowed by Freshwater northwards to the Solent, a direct outfall to the sea; and the streams thus intercepted at a high level, under the changed condition of flow, have originated the *Chines*. The gravel cliff of the Foreland, at the eastern end of the Isle of Wight, consists principally of raised shingle, which towards the south thins out, and is overlain by a thick deposit of brick-earth, a continuation of which caps the cliffs up to the chalk, and in which a flint implement was found by the author at 85 feet above the sea.

General Considerations.—The marine gravel, with granite boulders covering the south of Sussex, is continued westward by the gravel with similar boulders covering Portsea Island; and this again by the Hill-head gravels, with large blocks of Sarsen stone, these lower gravels being bordered on the south by the raised shingle deposits of the Isle of Wight, and on the north by the higher marine gravels of Avisford, Waterbeach, and Bourne, from which the lower gravel is divided by a well-marked step, extending beyond Portsdown Hill to Titchfield, and traceable on the west of Southampton Water. The Hill-head gravels are considered to be an estuarine deposit, of the same age as the marine gravels of Sussex, and the low-level gravels of the river-valleys; they are supposed to have been formed when the Isle of Wight was still joined to the main land, and all the rivers now reaching the sea by Poole Harbour, Christchurch Harbour, Southampton Water, &c., were affluents of a river communicating with an estuary opening to the sea in the direction of Spithead. The gravels lying above the step, such as those of Avisford and Waterbeach, Titchfield Common, Beaulieu Heath, and Bournemouth, are looked upon as equivalent in position and age to the high-level valley gravels. The level of the gravels on the highest parts of the table-lands is such as to indicate an age far greater than that of the highest gravels of the river-valleys; but the uniform surface from the 400-feet level downwards points to a long continuance of similar conditions, during which the gravel from the highest levels to that of the Bournemouth Cliffs was deposited. The area that can with any probability be assigned to the catchment basin of a river such as that which has been before alluded to, is only three-quarters of the basin of the Thames above Hampton, within which it is difficult to imagine that such an extent of gravel could have been spread out; and the inclination of the flattest of the table-lands is for a river such as only mountain-streams have, and quite incompatible with the spreading out of large even surfaces more than twenty miles across. It is considered more probable that the materials of the gravel were brought down from the chalk country on all sides by rivers, and spread out in an inlet of the sea shut in on the south, and opening out eastwards. This view is not without difficulties; it involves a gradual upheaval of the land, which, when the highest gravels now remaining were being spread out at or near the sea-level, must have stood more than 400 feet lower; and a considerable part of this upheaval must have taken place since the formation of the gravel in which implements fashioned by man are imbedded.

2. "On the relative position of the Forest-bed and the Chillesford Clay in Norfolk and Suffolk, and on the real position of the Forest-bed." By the Rev. John Gunn, M.A., F.G.S.

The author commenced by stating that both at Easton Bavent and at Kessingland the Forest-bed is to be seen forming part of the beach, or of the foot of the cliff, and underlying the Chillesford Clay. He considered that the soil of the Forest-bed had been deposited in an estuary, and that after its elevation the trees, of which the stools are now visible along the coast, grew upon it, and the true Forest-bed was formed. After the submergence of this first freshwater, then fluvio-marine, and finally marine deposits were formed upon it; and the author proposed to give the whole of these deposits the name of the "Forest-bed series." The author suggested that the Forest-bed itself is represented inland by the stony bed which lies immediately upon the chalk and between it and the Fluvio-marine and Marine Crags, his theory being that the surface of the chalk, after supporting a forest-bed fauna, was gradually covered up by successive crag deposits.

3. "On *Proterosaurus speneri*, von Meyer, and a new species, *Proterosaurus huxleyi*, from the Marl-slate of Midderidge, Durham." By Albany Hancock, F.L.S., and Richard Howse. Communicated by Prof. Huxley, F.R.S., F.G.S.

In this paper the authors described a specimen which they referred to *Proterosaurus speneri*, von Meyer; and one of a smaller form, which they regarded as new, and described as *Proterosaurus huxleyi*. Both were from the same part of the marl-slate of Midderidge, Durham. The two species agree in having the limbs and tail long and the neck long, and composed of seven vertebræ, in the number of dorsal vertebræ, in the number and character of the bones of the hand, and in some other particulars, sufficient, with these, in the opinion of the authors, to justify the reference of both to the genus *Proterosaurus*. In *P. huxleyi* the ribs are flattened instead of rounded at the proximal extremity, and less widened and grooved at the distal extremity than in *P. speneri*; the hind limb is considerably longer in proportion to the fore limb: and the distal extremity of the humerus is only twice as wide as the constricted part, instead of three times, as in the old species.

Chemical Society, June 16.—Prof. Williamson, F.R.S., president, in the chair. L. A. Lucas and A. W. Bickerton were elected Fellows. Mr. James Bell read a paper on "Fermentation." The author has instituted a series of experiments to determine: 1. The forms of natural ferment which various albuminous bodies will give rise to in solutions of cane sugar, and of cane sugar and glucose. 2. The relative fermentative powers of various ferments, especially of those occurring in malt extract and in the grape juice. 3. The influence of change of soil upon the fermentative organisms. From among the manifold results obtained in these experiments, the following may be mentioned: (*a*) Addition of glucose to fermenting liquids, especially to the juice of grape, is advantageous, inasmuch as it assists to exhaust the juice of its fermentative element, and thus imparts to the wine a greater keeping power. (*b*) Each ferment has its favourite soil. The President, in proposing a vote of thanks to the author, took occasion to give a brief *résumé* of the present state of knowledge of the yeast plant. Though called a "plant," the yeast organism appears in all its functions rather animal than vegetable; the products of its secretion are less complicated than those it takes in; it does not, like plants, require light for its vital process, neither does it absorb heat, but on the contrary gives it off. Alluding, then, to Liebig's recent memoir on fermentation, Prof. Williamson observed that that distinguished chemist had entirely dropped his former notions regarding the process of fermentation.—Dr. Heisch communicated a paper "On organic matter in water." The author was some time ago called on to assist a large manufacturer of lemonade, who suddenly found it impossible to make lemonade that would keep. After a day or two it became turbid, and its odour anything but agreeable. On investigating the liquid under the microscope it was found full of small spherical cells with, in most cases, a very bright nucleus. After examining all the materials employed, the fault was detected to be with the water. On putting a few grains of pure crystalline sugar into some of the water, it became turbid in a few hours, and contained the cells above mentioned. On inquiry it turned out that the well from which the water used in the preparation of the lemonade was obtained, had been slightly contaminated with sewage. This led the experimenter to mix a minute quantity of sewage with a sugar solution; the cells very soon made their appearance. Filtration through the finest Swedish paper does not remove the germs. Boiling for half an hour in no way destroys their vitality. Filtration through a good bed of animal charcoal seems to be the only effectual mode of removing them, but it is necessary to air the charcoal from time to time, else it loses its purifying property.—Mr. Perkins read a letter from Prof. Strecker, wherein the latter claims the priority of having published the true formula of alizarin as early as 1866, a fact which was not mentioned by Mr. Perkin in his recent lecture on alizarin. Mr. Perkin said that this omission was due to an oversight on his part, certainly not to any intention to deprive Professor Strecker of his merits.—Mr. Herman read a paper "On the methods for the determination of carbon in steel." Several samples of steel were analysed according to different methods, with the view of ascertaining which of the usual processes for determining the carbon in iron is the most advantageous. A large number of careful experiments led to the conclusion that the direct burning of the iron filings in a stream of oxygen (Wöhler's process) is the most expeditious and accurate method. In the following table the means of the results obtained by the different methods are given, the quantities of ferric oxide obtained by combustion in oxygen are almost identical with those required by theory.

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
By Eggertz's method	1·319	·789	·701	·587	·486	·349	·283	
By combustion in oxygen	1·1656	·7602	·635			·3594	·273	·9215
By Elliott's method	1·248	·8065	·724	·6701	·5025	·4772	·349	·9427

PARIS

Academy of Sciences, June 13.—The following mathematical papers were read:—Demonstration of Jacobi's method for the formation of the period of a primitive root, by M. V. A. Le Besque; on the construction of the axis of curvature of the developable surface, enveloping a plane of which the displacement is subjected to certain conditions, by M. A. Mannheim, communicated by M. Chasles; and on a certain family of curves and surfaces, by MM. F. Klein and S. Lie, also presented by M. Chasles.—MM. Jamin and Amaury presented a note on the specific heat of mixtures of alcohol and water, in which they show by the examination of numerous mixtures that the specific heat of such fluids is not only higher than the mean specific heat of their constituents, but that in certain proportions it even exceeds that of water.—M. Bussy remarked that M. Buignet and himself had previously ascertained that a mixture of equivalent parts of alcohol and water had a specific heat greater than the mean of its elements.—MM. C. Martins and G. Chancel presented a second note on the physical phenomena which accompany the rupture of hollow projectiles of various calibres by the congelation of water, in reply to observations made by General Morin and MM. Dumas and Elie de Beaumont on their former communication.—A note by M. J. Violle, on the mechanical equivalent of heat, was presented by M. H. Sainte-Claire Deville.—M. A. Houzeau communicated some experiments on the electrolisation of the air or of oxygen as a means of producing ozone. He stated that the production of ozone is greater at the negative than at the positive pole, that it increases with the electrical intensity but only to a certain extent with the duration of the experiment, that its formation is not prevented by the envelopment of the poles in glass tubes, and increases considerably with diminution of temperature, and that the ozone produced in air contains small quantities of nitrous compounds, which do not occur in that furnished by pure oxygen.—M. de Saint-Venant presented a note by M. J. Boussinesq on the theory of the flow of a liquid through an orifice in a thin wall.—The ephemeris of the newly-observed comet was communicated by M. Le Verrier from a letter of M. Winnecke's.—An extract from a letter from M. Bourgogne, giving an account of a storm which burst on the 29th of May in the neighbourhood of Alais, was communicated by M. Dumas. The hailstones were as large as small walnuts, and the damage done to the vegetation was immense.—A note on the spirting (*rochage*) of the carburets of iron, and on the sparks produced by these metals, with remarks on some new properties of iron, was read by M. H. Caron.—Some researches on platinum, by M. P. Schützenberger, were presented by M. H. Sainte-Claire Deville. This paper related to two compounds previously described by the author, namely, chloro-platinite of carbonyle, and chloro-platinite of dicarbonyle, $C\,O\,Pt\,Cl^2$ and $C^2O^2\,Pt\,Cl^2$, which he stated may be regarded as the chlorides of two diatomic compound radicals, platoso-carbonyle (C O, Pt) and platoso-dicarbonyle $\left(\begin{smallmatrix}CO\\CO\end{smallmatrix} > Pt\right)$. He described the behaviour of these compounds when treated with ammonia and ethylene, and also the action of protochloride of phosphorus upon subchloride of platinum, and of perchloride of phosphorus upon platinum.—A long and elaborate paper on tribromhydrine, by M. L. Henry, was read, and a note by M. Gobley, on the action of ammonia upon lecithine, was presented by M. A. Wurtz. He has found that lecithine in presence of ammonia gives origin to margaramide, to phosphoglyceric acid, and to choline.—M. C. Robin presented a note by MM. Lebert and Cohn, upon a new species of *Peronospora*, parasitic on cacti. The species, which the authors named *P. cactorum*, attacked several specimens of *Melocactus* and *Cereus giganteus*, in General

Jacobi's collection, and affected them with a putrefactive disease analogous to that of the potato, in which a *Peronospora* also takes part.—A note by M. E. F. Marey, "On the mechanism of the flight of birds," was communicated by M. H. Sainte-Claire Deville, to which we have adverted in another column.—A note by M. E. Perrin, presented by M. de Quatrefages, contained observations on the scissiparous reproduction of the Naïdea, as evinced in the genus *Dero*.—Other papers communicated were a note by M. Yvon Villarceau, "On the decimal division of angles and of time;" a note by M. Morache, "On the use of creosote in the treatment of typhoid fever;" one by M. Pegrani, "On the relation of the sympathetic nerve to the secretion of urine;" and one by M. Duboux, "On a new sign of death."

BOSTON

Natural History Society, March 16.—The secretary read the following observations of Mr. L. Trouvelot, upon the tendency of trees to bend toward the east. In the *Scientific American*, of March 5th, 1870, is inserted a paragraph headed "The Growth of Tree Trunks." It is there stated that a French naturalist had been measuring the tree trunks in a forest, and had found them all broader in the east-west than in the north-south direction, while another arborist of Toulouse, similarly gauging the trees, found the greatest swelling of their trunks towards the east-south-east; the former attributing this want of symmetry to the rotation of the earth, while the latter thinks that it is due to the early action of the sun upon the sap. As this paragraph reminded me of some observations which I made some five or six years ago, and which bear closely upon the same subject, I will present them to the society, thinking they may have some value in a scientific as well as in a practical point of view. While in the country, if we observe attentively the tree tops, we shall soon perceive that many species seem affected by a steady wind, though there is not the least breeze to be felt. Soon we notice that the branches of a great many trees have a general tendency to obey an unknown force which bends their extremities towards the east, or perhaps more correctly, in a direction perpendicular to the magnetic meridian. This bending of small branches cannot be observed so plainly upon all kinds of trees; some species having it well marked in every instance, while other species have it less visible, and even some others not at all noticeable. Most prominent for this peculiarity is the cherry tree, sometimes bending its branches towards the east, from head to foot. Next to this come the maple, the button wood tree (*Platanus*), then the pear tree, then the oak, etc. In the last named it is not always noticeable, though if the tree is isolated from others it is very plain in every instance. With the cherry tree it is so certain, that one could almost invariably determine the cardinal points by looking at the direction of its branches. At first I thought this might be due to the action of the prevailing winds, but this hypothesis was somewhat shaken, when I saw in many instances cherry trees sheltered entirely from the west winds by high blocks of houses within a few feet of them, exhibiting the same phenomenon. Whether this direction of the branches of trees is to be attributed to the prevailing winds, or to the rotation of the earth upon its axis, or to the heat or light of the sun, or again, to terrestrial magnetism, I shall not inquire at present, not having sufficient data to establish any theory. It would be of value, I venture to say, if observers would direct attention to this subject, and see if the direction is the same all over the globe, or if it is a local phenomenon, and also ascertain what species of trees obey this unknown force. It is not only in a theoretical point of view that this observation has some value; there is in it a practical lesson for the cultivators of shade and fruit trees. Soon after my observations, it struck me that something practical could be derived from this truth. All country people know by experience—sometimes dearly bought—that the transplantation of trees does not always succeed, and especially when the transplanted trees have arrived at a certain age. Fruit growers tell us that the cherry tree is one of those least likely to live when transplanted, while the apple tree will almost invariably succeed. My observations on many thousand cherry trees have shown me that this tree is very sensitive to the unknown force, while the apple tree is a great deal less so, and it is very seldom that an indication of bending will be seen. Has not this anything to do with success in transplanting? If, without regard to the direction of the branches of a cherry tree, we set this tree in a position contrary to the one it occupied before, its branches now bending towards the west, then it is plain that the force which gave it the bend is acting in an opposite direction, in consequence of which the tree is suffering. But with the apple tree it is different, as this is far less sensitive; therefore it will not suffer much. Ten years ago I bought a fine cherry tree and transplanted it to my garden, of course without regard to direction; the tree is now living; it has not grown a particle: there has not been one inch of new wood added to the length of its twigs since it was put there; the branches have no bend. Five years ago another cherry tree from the same place was also transplanted in my garden; the tree is now treble the size of the other, its branches are strongly bent east. Why this difference? Was the one set in a suitable position, and the other not? I could not tell. But here is something more positive. Three years ago I saw in Malden twenty beautiful pear trees transplanted with the greatest care; all these trees were of pretty good size, being some years old, and they all bent very strongly. They were set without regard to direction; five or six of these trees happened to be placed in about the position which they must have had when growing, the remainder were set in all directions. I went many times that way to watch the success of this small orchard. The very first year about one half were completely dead. The second year took five more, which had been languishing all the summer, and now five out of the twenty are living and in good condition, and strange to say, these five are those which were set with their branches dipping east. Do we owe their life to the fact that after being transplanted they occupied the same relative position with regard to the points of the compass as before, or is it only a curious coincidence? It is more than I can tell. My experience is not sufficient to allow an opinion in this matter; time will throw light upon the subject.

DIARY

FRIDAY, July 1.

Geologists' Association, at 8.

SUNDAY, July 3.

Sunday Lecture Society, at 8.—On Man's Cruelty to Man: Rev. Allen D. Graham.

MONDAY, July 4.

Entomological Society, at 7.
London Institution, at 4.—Botany: Prof. Balfour.
Royal Institution, at 2.—General Monthly Meeting of Members.

PASTEUR'S RESEARCHES ON THE DISEASES OF SILKWORMS

I HAVE recently received from M. Pasteur a copy of his new work, "Sur la Maladie des vers à soie," a notice of which, however brief and incomplete, will, I am persuaded, interest a large class of the readers of NATURE. The book is the record of a very remarkable piece of scientific work, which has been attended with very remarkable practical results. For fifteen years a plague had raged among the silkworms of France. They had sickened and died in multitudes, while those that succeeded in spinning their cocoons furnished only a fraction of the normal quantity of silk. In 1853 the silk culture of France produced a revenue of one hundred and thirty millions of francs. During the twenty previous years the revenue had doubled itself, and no doubt was entertained as to its future augmentation. "Unhappily, at the moment when the plantations were most flourishing, the prosperity was annihilated by a terrible scourge." The weight of the cocoons produced in France in 1853 was twenty-six millions of kilogrammes; in 1865 it had fallen to four millions, the fall entailing in the single year last mentioned a loss of one hundred millions of francs.

The country chiefly smitten by this calamity happened to be that of the celebrated chemist Dumas, now perpetual secretary of the French Academy of Sciences. He turned to his friend, colleague, and pupil, Pasteur, and besought him with an earnestness which the circumstances rendered almost personal, to undertake the investigation of the malady. Pasteur at this time had never seen a silkworm, and he urged his inexperience in reply to his friend. But Dumas knew too well the qualities needed for such an inquiry to accept Pasteur's reason for declining it. "Je met," said he, "un prix extrème à voir votre attention fixée sur la question qui interesse mon pauvre pays; la misère surpasse tout ce que vous pouvez imaginer." Pamphlets about the plague had been showered upon the public, the monotony of waste paper being broken at rare intervals by a more or less useful publication. "The Pharmacopœia of the Silkworm," wrote M. Cornalia in 1860, "is now as complicated as that of man. Gases, liquids, and solids have been laid under contribution. From chlorine to sulphurous acid, from nitric acid to rum, from sugar to sulphate of quinine,—all has been invoked in behalf of this unhappy insect." The helpless cultivators, moreover, welcomed with ready trustfulness every new remedy, if only pressed upon them with sufficient hardihood. It seemed impossible to diminish their blind confidence in their blind guides. In 1863 the French Minister of Agriculture himself signed an agreement to pay 500,000 francs for the use of a remedy which its promoter declared to be infallible. It was tried in twelve different departments of France and found perfectly useless. In no single instance was it successful. It was under these circumstances that M. Pasteur, yielding to the entreaties of his friend, betook himself to Alais in the beginning of June 1865. As regards silk husbandry, this was the most important department in France, and it was also that which had been most sorely smitten by the epidemic.

The silkworm had been previously attacked by *muscardine;* a disease proved by Bassi to be caused by a vegetable parasite. Muscardine, though not hereditary, was propagated annually by the parasitic spores, which, wafted by winds, often sowed the disease in places far removed from the centre of infection. According to Pasteur, muscardine is now very rare; but for the last fifteen or twenty years a deadlier malady has taken its place. A frequent outward sign of this disease are the black spots which cover the silkworms, hence the name pébrine, first applied to the plague by M. de Quatrefages, and adopted by Pasteur. Pébrine also declares itself in the stunted and unequal growth of the worms, in the languor of their movements, in their fastidiousness as regards food, and in their premature death. The discovery of the inner workings of the epidemic may be thus traced. In 1849 Guerin Méneville noticed in the blood of certain silkworms vibratory corpuscles which he supposed to be endowed with independent life, and to which he gave a distinctive name. As regards the motion of the particles, Filippi proved him wrong; their motion was the well-known Brownian motion. But Filippi himself committed the error of supposing the corpuscles to be normal to the life of the insect. They are really the cause of its mortality—the form and substance of its disease. This was studied and well described by Cornalia; while Lebert and Frey subsequently found the corpuscles not only in the blood, but in all the tissues of the silkworm. Osimo, in 1857, discovered the corpuscles in the eggs, and on this observation Vittadiani founded, in 1859, a practical method of distinguishing healthy from diseased eggs. The test often proved fallacious, and it was never extensively applied.

The number of these corpuscles is sometimes enormous. They take possession of the intestinal canal, and spread thence throughout the body of the worm. They fill the silk cavities, the stricken insect often going through the motions of spinning without any material to answer to the act. Its organs, instead of being filled with the clear viscous liquid of the silk, are packed to distension by these corpuscles. On this feature of the plague Pasteur fixed his attention. He pursued it with the skill which appertains to his genius, and with the thoroughness that belongs to his character. The cycle of the silkworm's life is briefly this:—From the fertile egg comes the little worm, which grows, and after some time casts its skin. This process of moulting is repeated two or three times at subsequent intervals during the life of the insect. After the last moulting the worm climbs the brambles placed to receive it, and spins among them its cocoon. It passes thus into a chrysalis; the chrysalis becomes a moth, and the moth when liberated lays the eggs which form the starting-point of a new cycle. Now Pasteur proved that the plague-corpuscles might be incipient in the egg, and escape detection; they might also be germinal in the worm, and still baffle the microscope. But as the worm grows, the corpuscles grow also, becoming larger and more defined. In the aged chrysalis they are more pronounced than in the worm; while in the moth, if either the egg or the worm from which it comes should have been at all stricken, the corpuscles infallibly appear, offering no difficulty of detection. This was the first great point made out in 1865 by Pasteur. The Italian naturalists, as aforesaid, recommended the examination of the eggs before risking their incubation. Pasteur showed that both eggs and worms might be smitten and still pass muster, the culture of such eggs or such worms being sure to entail disaster. He made the moth his starting-point in seeking to regenerate the race.

And here is to be noted a point of immense practical importance. The worms issuing from the eggs of perfectly healthy moths may afterwards become themselves infected through contact with diseased worms, or through germs mixed with the dust of the rooms in which the worms are fed. But though the moths derived from the worms thus infected may be so charged with corpuscles as to be totally unable to produce eggs fit for incubation, still Pasteur shows that the worms themselves, in which the disease is not hereditary, never perish before spinning their cocoons. This, as I have said, is a point of capital importance; because it shows that the moth-test, if acted upon, even though the worms during their "education" should contract infection, secures, at all events, the next subsequent crop.

Pasteur made his first communication on this subject to the Academy of Sciences in September 1865. It raised a cloud of criticism. Here forsooth was a chemist rashly quitting his proper *métier* and presuming to lay down the law for the physician and biologist on a subject which was eminently theirs. "On trouva étrange que je fusse si peu au courant de la question; on m' opposa des travaux qui avaient paru depuis longtemps en Italie, dont les resultats montraient l'inutilité de mes efforts, et l'impossibilité d'arriver à un resultat pratique dans la direction que je m'étais engagé. Que mon ignorance fut grande au sujet des recherches sans nombre qui avaient paru depuis quinze années." Pasteur heard the buzz, but he continued his work. In choosing the eggs intended for incubation, the cultivators selected those produced in the successful "educations" of the year. But they could not understand the frequent and often disastrous failures of their selected eggs; for they did not know, and nobody prior to Pasteur was competent to tell them, that the finest cocoons may envelop doomed corpusculous moths. It was not, however, easy to make the cultivators accept new guidance. To strike their imagination and if possible determine their practice, Pasteur hit upon the expedient of prophecy. In 1865 he inspected at St. Hippolyte-du-Fort fourteen different parcels of eggs intended for incubation. Having examined a sufficient number of the moths which produced these eggs, he wrote out the prediction of what would occur in 1867, and placed the prophecy as a sealed letter in the hands of the Mayor of St. Hippolyte.

In 1867 the cultivators communicated to the mayor their results. The letter of Pasteur was then opened and read, and it was found that in twelve out of fourteen cases, there was absolute conformity between his prediction and the observed facts. Many of the educations had perished totally; the others had perished almost totally; and this was the prediction of Pasteur. In two out of the fourteen cases, instead of the prophesied destruction, half an average crop was obtained. Now, the parcels of eggs here referred to were considered healthy by their owners. They had been hatched and tended in the firm hope that the labour expended on them would prove remunerative. The application of the moth-test for a few minutes in 1866 would have saved the labour and averted the disappointment. Two additional parcels of eggs were at the same time submitted to Pasteur. He pronounced them healthy; and his words were verified by the production of an excellent crop. Other cases of prophecy still more remarkable, because more circumstantial, are recorded in the work before us.

These deadly corpuscles were found by Leydig in other insects than the silkworm moth. He considers them to belong to the class of psososperms founded by J. Müller. "This," says Pasteur, "is to regard the corpuscular organism as a kind of parasite, which propagates itself after the manner of parasites of its class." Pasteur subjected the development of the corpuscles to a searching examination. With admirable skill and completeness he also examined the various modes by which the plague is propagated. He obtained perfectly healthy worms from moths perfectly free from corpuscles, and selecting from them 10, 20, 30, 50, as the case might be, he introduced into the worms the corpusculous matter. It was first permitted to accompany the food. Let us take a single example out of many. Rubbing up a small corpusculous worm in water, he smeared the mixture over the mulberry leaves. Assuring himself that the leaves had been eaten, he watched the consequences from day to day. Side by side with the infected worms he reared their fellows, keeping them as much as possible out of the way of infection. These constituted his "lot temoign," his standard of comparison. On the 16th of April, 1868, he thus infected thirty worms. Up to the 23rd they remained quite well. On the 25th they seemed well, but on that day corpuscles were found in the intestines of two of the worms subjected to microscopic examination. The corpuscles begin to be formed in the tunic of the intestine. On the 27th, or eleven days after the infected repast, two fresh worms were examined, and not only was the intestinal canal found in each case invaded, but the silk organ itself was found charged with the corpuscles. On the 28th the twenty-six remaining worms were covered by the black spots of pébrine. On the 30th the difference of size between the infected and non-infected worms was very striking, the sick worms being not more than two-thirds of the size of the healthy ones. On the 2nd of May a worm which had just finished its fourth moulting was examined. Its whole body was so filled with corpuscles as to excite astonishment that it could live. The disease advanced, the worms died and were examined, and on the 11th of May only six out of the thirty remained. They were the strongest of the lot, but on being searched they also were found charged with corpuscles. Not one of the thirty worms had escaped; a single corpusculous meal had poisoned them all. The standard lot, on the contrary, spun their fine cocoons, and two only of their moths were found to contain any trace of corpuscles. These had doubtless been introduced during the rearing of the worms.

As his acquaintance with the subject increased, Pasteur's desire for precision augmented, and he finally gives the growing number of corpuscles seen in the field of his microscope from day to day. After a contagious repast the number of worms containing the parasite gradually augmented until finally it became cent. per cent. The number of corpuscles would at the same time rise from 0 to 1, to 10, to 100, and sometimes even to 1,000 or 1,500 for a single field of his microscope. He then varied the mode of infection. He inoculated healthy worms with the corpusculous matter, and watched the consequent growth of the disease. He showed how the worms inoculate each other by the infliction of visible wounds with their "crochets." In various cases he washed the "crochets," and found corpuscles in the water. He demonstrated the spread of infection by the simple association of healthy and diseased worms. In fact, the diseased worms sullied the leaves by their dejections, they also used their crochets, and spread infection in both ways. It was no hypothetical infected medium that killed the worms, but a definitely-organised and isolated thing. He examined the question of contagion at a distance, and demonstrated its existence. In fact, as might be expected from Pasteur's antecedents, the investigation was exhaustive, the skill and beauty of his manipulation finding fitting correlatives in the strength and clearness of his thought.

Pébrine was an enigma prior to the experiments of Pasteur. "Place," he says, "the most skilful educator, even the most expert microscopist, in presence of large educations which present the symptoms described in our experiments; his judgment will necessarily be erroneous if he confines himself to the knowledge which preceded my researches. The worms will not present to him the slightest spot of pébrine; the microscope will not reveal the existence of corpuscles; the mortality of the worms will be null or insignificant; and the cocoons leave nothing to be desired. Our observer would, therefore, conclude without hesitation that the eggs produced will be good for incubation. The truth is, on the contrary, that all the worms of these fine crops have been poisoned; that from the beginning they carried in them the germ of the malady; ready to multiply itself beyond measure in the chrysalides and the moths, thence to pass into the eggs and smite with sterility the next generation. And what is the first cause of the evil concealed under so deceitful an exterior? In our experiments we can, so to speak, touch it with our fingers. It is entirely the effect of a single corpusculous repast; an effect more or less prompt according to the epoch of life of the worm that has eaten the poisoned food."

It was work like this that I had in view when, in a lecture which has brought me much well-meant chastisement from a certain class of medical men, and much gratifying encouragement from a different class, I dwelt on the necessity of experiments of physical exactitude in testing medical theories. It is work like this which might be offered as a model to the physicians of England, many indeed of whom are pursuing with characteristic skill and energy the course marked out for them by this distinguished master. Prior to Pasteur, the most diverse and contradictory opinions were entertained as to the contagious character of pébrine; some stoutly affirmed it, others as stoutly denied it. But on one point all were agreed. "They believed in the existence of a deleterious medium, rendered epidemic by some occult and mysterious influence, to which was attributed the cause of the malady." Between such notions and the work of Pasteur, no physically-minded man will, I apprehend, hesitate in his choice.

Pasteur describes in detail his method of securing healthy eggs, which is nothing less than a mode of restoring to France her ancient prosperity in silk husbandry. And the justification of his work is to be found in the reports which reached him of the application, and the unparalleled success of his method, at the time he was putting his researches together for final publication. In France and Italy his method has been pursued with the most surprising results. It was an up-hill fight which led to this triumph, but it is consoling to think that even the stupidities of men may be converted into elements of growth and progress. Opposition stimulated Pasteur, and thus, without meaning it, did good service. "Ever," he says, "since the commencement of these researches, I have been exposed to the most obstinate and unjust contradictions; but I have made it a duty to leave no trace of these contests in this book." I have met with only a single allusion to the question of spontaneous generation in M. Pasteur's work. In reference to the advantage of rearing worms in an isolated island like Corsica, he says:—"Rien ne serait plus facile que d'éloigner, pour ainsi dire, d'une manière absolue la maladie des corpuscles. Il est au pouvoir de l'homme de faire disparaître de la surface du globe les maladies parasitaires, si, comme c'est ma conviction, la doctrine des générations spontanées est une chimère." It is much to be desired that some really competent person in England should rescue the public mind from the confusion now prevalent regarding this question.

M. Pasteur has investigated a second disease, called in France *flacherie*, which has co-existed with pébrine, but which is quite distinct from it. Enough, I trust, has been said to send the reader interested in these questions to the original volumes for further information. I report with deep regret the serious illness of M. Pasteur; an illness brought on by the labours of which I have tried to give some account. The letter which accompanied his volumes ends thus:—"Permettez-moi de terminer ces quelques lignes que je dois dicter, vaincu que je suis par la maladie, en vous faisant observer que vous rendiez service aux Colonies de la Grande Bretagne en repandant la connaissance de ce livre, et des principes que j'établis touchant la maladie des vers à soie. Beaucoup de ces colonies pourraient cultiver le mûrier avec succès, et en jetant les yeux sur mon ouvrage vous vous convaincrez aisement qu'il est facile aujourdhui, non seulement d'éloigner la maladie régnante, mais en outre de donner aux récoltes de la soie une prospérité qu'elles n'ont jamais eue."

Royal Institution, 30th June JOHN TYNDALL

WHAT IS ENERGY?

III.

THE CONSERVATION OF ENERGY

IT is well-known that certain organisms of the animal world do not confine themselves to one state of being or to one order of existence, and the most familiar instance of this roving habit of life is the caterpillar, which passes first into the chrysalis state, and after that into the butterfly. This habit is not, however, peculiar to the organic world, for energy delights in similar transmutations, and we have just seen how the eminently silent and invisible electrical current may occasionally be transmuted into the vivid, instantaneous, awe-inspiring flash of lightning. Nor is this element of change confined to our peculiar corner of the universe, but it extends itself to remote starry systems, in some of which there is a total extinction of luminosity for a while, to be succeeded by a most brilliant luminous outburst, presenting all the appearance of a world on fire.

We shall not enter here into great detail regarding the various changes of energy from one form into another; suffice it to say, that amid all these changes of form, and sometimes of quality, the element of *quantity* remains the same. Those of our readers who are mathematicians know what is meant by variable quantities, for instance, in the equation $x+y+z=A$, if x, y, & z are variable and A constant, you may change x into y and into z, and y into x and into z, and in fact perform any changes you choose upon the left hand side of your equation, *provided that* you keep their sum always constant and equal to A. It is precisely thus in the world of energy; and the invariability of the sum of all the energies of the universe forms the doctrine known as the "conservation of energy." This doctrine is nothing else than an intelligent and scientific denial of the chimera of perpetual motion.

Recognising the great importance of work, it was natural enough at an early stage of our knowledge that enthusiasts should endeavour to create energy or the power of doing work, that is to say, endeavour to construct a machine that should go on working for ever without needing to be supplied with fuel in any way, and accordingly inventors became possessed with the idea that some elaborate system of machinery would, no doubt, give us this grand desideratum, and men of science have been continually annoyed with these projects, until in a moment of inspiration they conceived the doctrine of the conservation of energy!

It flows from this doctrine that a machine is merely an instrument which is supplied with energy in one form, and which converts it into another and more convenient form according to the law of the machine.

We shall now proceed to trace the progress of energy through some of its most important transformations. To begin with that one to which we have already alluded, what becomes of the energy of a falling body after it strikes the earth? This question may be varied in a great number of ways. We may ask, for instance, what becomes of the energy of a railway train when it is stopped? what becomes of the energy of a hammer after it has struck the anvil? of a cannon ball after it has struck the target? and so on.

In all these varieties we see that either percussion or friction is at work; thus it is friction that stops a railway-train, and it is percussion that stops the motion of a falling stone or of a falling hammer, so that our question is in reality, what becomes of the energy of visible motion when it has been stopped by percussion or friction?

Rumford and Davy were the pioneers in replying to this important question. Rumford found that in the process of boring cannon the heat generated was sometimes so great as to boil water, and he supposed that work was changed into heat in the process of boring. Davy again melted two pieces of ice by causing them to rub against each other, and he likewise concluded that the work spent on this process had been converted into heat.

We see now why by hammering a coin on an anvil we can heat it very greatly, or why on a dark night the sparks are seen to fly out from the break-wheel which stops the motion of the railway train, or why by rubbing a metal button violently backwards and forwards against a piece of wood we can render it so hot as to scorch our hand, for in all these cases it is the energy of visible motion which is being converted into heat.

But although this was known nearly a century ago, it was reserved for Joule, an English philosopher of the present day, to point out the numerical relation subsisting between that species of energy which we call visible motion and that which we call heat.

The result of his numerous and laborious experiments was, that if a pound of water be dropped from a height of 772 feet under the influence of gravity, and if the velocity which it attains be suddenly stopped and converted into heat, this heat will be sufficient to raise the whole mass 1° Fahr. in temperature.

From this he concluded that when a pound of water is heated 1° Fahr. in temperature, an amount of molecular energy enters into the water which is equivalent to 772 foot-pounds, that is to say, to one pound raised 772 feet high against the influence of gravity, or allowed to fall 772 feet under the same influence.

He found again that if a pound of water were to fall twice this distance, or 1,544 feet under gravity, the velocity if stopped would raise its temperature 2° Fahr., and in fact that the rise of temperature under such circumstances is proportional to the height from which the pound of water is supposed to fall. By this means an exact relation is established between heat and work. Grove was the first to point out the probability of a connection between the various species of molecular energy; and the researches of Joule, Thomson, and others, have established these relations with numerical accuracy. No better example of the correlation of the various kinds of energy can be given than what takes place in a galvanic battery. Let us suppose that zinc is the metal used. Here the source of energy is the burning or chemical combination of the zinc with oxygen, &c., in order to form a salt of zinc. The source of energy is in fact much the same as when coal is burned; it is the energy produced by chemical combination. Now, as we have said, the zinc combines with the oxygen, and sulphate of zinc is produced, but the result of this combination does not at first exhibit itself in the form of heat, but rather in that of an electric current. No doubt a great portion of the energy of this electric current is ultimately spent in heat, but we may, if we choose, spend part in promoting chemical decomposition; for instance, we may decompose water. In this case part of the energy of the battery, derived as has been stated from the burning of the zinc, is spent in heat and part in decomposing the water, and hence we shall have less heat than if there were no water to decompose. But if when we have decomposed the water, we mix together the two gases hydrogen and oxygen which are the results of this decomposition, and explode them, we shall recover the precise deficiency of heat. Without the decomposition, let us say that the burning in the battery of a certain weight of zinc gives us heat equal to 100, but with the decomposition only 80, twenty units of energy have therefore become spent in the decomposition, but if we explode the mixture of gases procured from the decomposition we shall get back heat equal to 20, and thus make the whole result of the burning of the zinc 100 units of energy as before.

In like manner, if our electric battery is made to do work, thus forming a kind of engine, we shall have the heat produced by the current diminished by the exact equivalent of the mechanical effect which we have obtained from this engine.

There is nothing for nothing in the universe of energy.

B. STEWART

ROUMEGUERE ON FUNGI

Cryptogamie Illustrée, ou Histoire des Familles naturelles des Plantes Acotyledonées d'Europe. Famille des Champignons. Par Casimir Roumeguère. (Paris: J. B. Baillière. 1870.) 4to., pp. 164, figures 1700.

THE numerous introductions to the study of fungi, whether as articles of food, objects of physiological and botanical interest, or as the cause or aggravator of disease both in the animal and vegetable world, which are constantly issuing from the press, or whose speedy appearance is announced, are a certain proof of the daily increasing appreciation of the importance of a tribe which has often been considered as the mere offscourings of the earth, and worthy only of the title of "abominations." These publications of course are of very different value, and the glowing terms in which they are announced sometimes lead only to disappointment after an inconvenient outlay. As a striking instance, Valenti-Serini's work on doubtful or poisonous fungi of the neighbourhood of Turin may be mentioned, which was characterised in the "Annals of Natural History" as "this important work," its true characters being admirably exposed by Mr. Worthington Smith in "Seemann's Journal of Botany;" and unsparing as the remarks are, I consider that they are completely justified. It is simply a disgrace to the Academy under whose auspices it is published.*

This is not, however, the case with the publication whose title is given above; for though it is far from being free from faults, and the illustrations, though selected with considerable skill, are in some cases so coarse as almost to render them useless; still there is such a mass of information as may make it acceptable even to those who are well versed in the subject; and though unfortunately the several matters which come under review are seldom thoroughly worked out, yet they indicate the proper line of research and the best sources of information, in such a manner as to ensure it a hearty welcome. Every possible nook and corner of the mycological library seems to have been thoroughly ransacked, and that without any national prepossession such as occasionally detracts from the credit even of highly approved authorities. Indeed I was not a little surprised to find how diligently English works on the subject had been sifted, and not the less to recognise an allusion even to a sectional address at Norwich, though the remarks of its author have not been quite correctly interpreted.

It is not likely that there should be much novelty in so unpretentious a work, and perhaps it may be as well that no new views should be propounded, founded on imperfect data. It is a great matter to find no glaring errors likely to mislead; though here and there the drift of what has been written may have been misunderstood.

* I need only refer to Tab. 30 to justify this remark; and this instance is not a solitary one.

It is scarcely possible to overrate the importance of the study of fungi in any of the points of view which were enumerated. The Society of Arts and the Horticultural Society of London have very properly called attention to the great importance of fungi as articles of food, by encouraging inquiry or offering rewards for the best collections of esculent, doubtful, and poisonous species. The South Kensington Museum has also done its part. The very faithful set of drawings by Mr. W. G. Smith, exhibited on its walls, and the admirably prepared specimens by Mr. English—which retain their form perfectly, and, to a great extent, their proper colours—must eventually facilitate the due discrimination, which, as in the case of other vegetable esculents, must be matter of experience. It is quite lamentable to reflect what a vast quantity of wholesome food, and food which, from its chemical composition, may profitably replace the consumption of meat in the labourer's family, is utterly neglected, either from ignorance or prejudice.

In the second point of view as regards their physiological and botanical interest, it need only be mentioned with respect to the former, that, with the exception of the true algæ, the phenomena of impregnation cannot be studied more profitably than in those wonderful plants which occur on dead animals or decaying vegetables in water, and which are, undoubtedly, aquatic forms of various moulds, though in some respects they approach the algæ. Then as respects a biological point of view, the question of the origin of atmospheric germs, one of the most difficult of solution which can engage the attention of the microscopist, and which, in my opinion, has never been carried out so as to trace *accurately*, and free from all doubt, the development of the minute bodies which occur in fluids, whether of organic or inorganic composition, into higher forms; while the botanist will find a variety of form and structure which is scarcely surpassed in the higher branches of the science.

As regards the third point. If we consider fungi as the causes or aggravators of disease, it may be remarked, that, notwithstanding all that has been written on the subject, a great deal still remains to be discovered. The dreadful forms of Erysipelas and Hospital Gangrene, which occur so fatally in London hospitals, are, in all probability, dependent somehow on fungi, though the matter has not, hitherto, been found capable of proof, and whatever may be thought of Dr. Tyndall's views, the medical world cannot be too thankful to him for bringing the matter so prominently before the public.* The same also may be said with respect to Dr. Hallier's speculations, though, as I believe, they have been justly challenged both here and on the Continent.

A great deal is known about the influence of fungi in the production of disease in plants, but much more remains to be discovered. It may, eventually, prove that

* That the reproductive bodies of the larger fungi and moulds are widely carried about by the air, will be very evident to any one who has seen the clouds of spores which, in some cases, arise like smoke on the least agitation. Some years ago two flakes of snow were sent to me from Hampstead, prepared as microscopic objects, with the intention of exhibiting the organic matters which they might carry down with them in their course, and both, undoubtedly, contained perfect spores of fungi. Much more then may we expect that organisms which do not exceed a thirtieth or a fiftieth part of their diameter, and which are quite invisible except under very high magnifying powers, should be present everywhere to perform their functions as putrefactive ferments.

some of the more obscure cases of vegetable pathology depend on the minute fermentative bodies which, it should seem, play such an important part in animals. Certain it is that yeast globules and bacteria occur in vegetables where there is, apparently, no immediate communication with the atmosphere, or where, at least, it is as obscure as in some cases which engage the attention of the students of animal biology. Matters which have been long since ascertained to be facts, are still challenged by incompetent and uninstructed observers, and every one who can remove any portion of the prejudices which so materially retard the progress of science, will be doing a good work.

It is to be regretted that the quarto form of the work before us makes it very inconvenient for students, and it is to be hoped that a revised edition in octavo will secure a wider circulation. M. J. BERKELEY

AMERICAN NATURAL HISTORY

The American Naturalist. A popular illustrated Magazine of Natural History. Vols. 1, 2, and 3, from March 1867, to February 1870. (Salem, Mass. Peabody Academy of Sciences. London: Trübner.)

WE have several distinct reasons for bringing this useful periodical before the notice of our readers. In the first place, American Naturalists and writers on science generally complain, and not altogether without reason, that many of the most important works that issue from the Transatlantic press are much less known in this country than their merits deserve. Our personal experience leads us to believe that this complaint is well founded. We lately applied in vain to the Libraries of the Royal Society, of the University of Cambridge, and of a Scottish University, for the *American Naturalist* and for Clark's "Mind in Nature;" and we suspect that very few copies of such books as the following are to be found in English libraries, namely, a complete set of the works of Agassiz since he went to America, Binney's "Terrestrial Mollusks of the United States," Gould and Binney's "Report on the Invertebrata of Massachusetts," Tooney and Holmes's "Fossils of South Carolina," Samuel's "Birds of New England," Dekay's "Fishes and Reptiles of New York," the reports on the Pacific and other Railway Surveys, and the numerous contributions to science published during the last few years, by Marsh, Lea, Leidy, Hall, Wynam Baird, Coues, Packard, Scudder, Le Conte, Stimpson, Verrill, and a host of other writers.

Our second and chief reason for noticing the *American Naturalist*, is on account of its intrinsic value. The three volumes now completed contain a series of important original contributions, by Professors Bailey, Cope, Edwards, Hayden, Henrichs, Orton, and Verrill, Drs. Brewer, Cooper, Coues, Hunt, Joseph Jones, Le Conte, Lincecum, Norton, A. S. Packard, Perkins, Wood, &c. Messrs. Brigham, Dall, Hartt, Hyatt, Lockwood, Morse, Russell, Scudder, and many others. Botany, Geology, Physical Geography, and Zoology, receive their due shares of attention, and in a scientific point of view, the articles occupy an intermediate position between those which we find in "The Annals of Natural History" and Hardwicke's "Science Gossip." Each number contains (1) Original Articles; (2) Reviews of Works on Natural History; (3) Natural History Miscellany, including recent discoveries in Geology, Botany, Zoology, and Microscopy, and terminating with answers to correspondents; (4) Proceedings of Scientific Societies; the whole concluding with a List of Books Received, and a glossary of all the scientific terms occurring in the current number.

If our readers require any further evidence of the value of this periodical, we may add that after one year's independent existence, it has been issued as a publication of the Peabody Academy of Sciences. The trustees "consider it one of the legitimate objects of their trust to assist in the publication of the *Naturalist* by advancing funds sufficient to enable the editors to continue its publication in an improved condition."

Our third and last reason for now urging the claims of this periodical is, that being informed by Messrs. Trübner and Co., to whom we are indebted for the loan of these volumes, that new subscribers can for a time obtain the parts already published at a reduced rate; this seems to be an excellent opportunity for natural history clubs and libraries, both to obtain the back volumes and to order the future numbers. G. E. D.

OUR BOOK SHELF

The Science and Art of Arithmetic, for the Use of Schools. Part I., Integral. By A. Sonnenschein and H. A. Nesbitt, M.A., University College, London. (London: Whittaker and Co.)

FORTY years have elapsed since the appearance of Prof. De Morgan's "Elements of Arithmetic," at a time when perhaps few teachers, as they submitted the rules of the science to their pupils, cared to establish them upon reason and demonstration. The effect of this work was that a rational arithmetic began to be taught generally, and the mere committing of rules to memory took its due subordinate position in the course of instruction. Such a method of treatment will go far to develop and exercise the reasoning powers, and in the case of many pupils, there is hardly any other subject which can so well be made a groundwork for the exercise of the reasoning faculty. The book before us is avowedly drawn up in agreement with the principles of Mr. De Morgan's work, and the aim of the authors is to lead the student "to the discovery of the several rules by some path such as an original discoverer might have travelled." In this first part, which treats of Integral Arithmetic, we consider that they have carried out their principles successfully, and hope they will succeed as well with the remaining two parts, which are to embrace respectively Vulgar Fractions and Approximate Calculations. The rules enunciated are few and tersely given; there is a great store of illustration; elementary difficulties are well stated and honestly grappled with, and cleared up in a way that brings the subject to the level of the capacities of junior students; at the same time advanced as well as young teachers may gather much that is useful from the book. A reader who has carefully gone through the work, can hardly fail to master the early details of the science; if he fail, it will not be the fault of the authors. The subjects treated of are numeration, modes of computation, the so-called first four rules, contracted operations, scales of notation, and properties of numbers. Under this last division we have much valuable matter grouped under the several heads of Divisibility of Numbers, Casting out Nines, Resolution into Prime Factors, Greatest Common Measure, and Least Common Multiple. Throughout and at the end of the work occur numerous examples, very varied, all of which are carefully arranged, and many fully worked out in two or more ways. With this short analysis of the contents, we heartily commend the work to teachers generally, assuming, of course, that they will regulate their use of it in proportion to the requirements of age and ability of their pupils. The work is neatly got up, and we have detected hardly any errata. On page 51, ex. 2, we have "How many petals are there in 376 forget-me-nots?" Here there is an omission and a slight technical error. In botanical language the "forget-me-not" (*Myosotis*) is monopetalous, the number of *lobes* of the corolla being *five*. R. T.

Transactions of the Woolhope Naturalists' Field Club for 1869.

NO slight service has been rendered to the cause of natural science by the numerous naturalists' field clubs scattered here and there through the country, not only in the exploration of the natural products of their respective districts during their summer excursions, but in infusing a love of such pursuits among dwellers in the country. When the transactions of the year are published in so attractive a form as the volume before us, an additional benefit is conferred. The Woolhope Club is one which has been for some years favourably known, chiefly through the labours of one or two genuine naturalists among its members, as having furnished some real contributions to science by its researches among the pleasant woodland county of Herefordshire. The volume consists mainly of lively accounts of the various excursions made by the club during the summer of 1869, with lists of the rarities, zoological and botanical, met with, and reports of the papers read by its members. Among the more important of the latter we may mention Dr. Bull's history of "The Ancient Forest of Deerfold;" and papers on the occurrence and identification of rare birds in Herefordshire and Radnorshire, by Mr. Armitage, Rev. Clement Ley, and Mr. James W. Lloyd, including the peregrine falcon (*Falco peregrinus*), the hobby (*F. subbuteo*), the little merlin (*F. æsalon*), the grasshopper warbler (*Sylvia locustella*), the fire-crested wren (*Regulus ignicapillus*), and the great and little bittern (*Ardea stellaris* and *minuta*). Dr. Bull has given a celebrity to the Woolhope Club for its enthusiasm in favour of edible fungi; there are several papers on the subject, to which is appended Mr. W. G. Smith's *Clavis Agaricinorum*. Several very pretty illustrations ornament the book, among which may be mentioned photographs of some of the remarkable trees of Herefordshire, and a drawing of the famous Deerfold mistletoe-oak.

Contributions to Botany, Iconographic and Descriptive. By John Miers, F.R.S., F.L.S. Vol. II. (Williams and Norgate, 1869.)

THIS volume will be welcomed as an addition to Mr. Miers' contributions to systematic and structural botany, all of which possess the value of the labours of a careful and accurate observer, and one especially conversant practically with South American botany. We find in this volume carefully worked papers on the *Calyceraceæ*, a small order closely allied to *Compositæ*, on the carpological structure of *Bignoniaceæ*, on the history of the maté plant, and the different species of ilex used in the preparation of Paraguay tea, a monograph of the *Tricuspidarieæ*, an essay on the genus *Goupia*, one on the structure of *Heliotropiaceæ*, and a paper on the South American forms of *Ehretiaceæ*. But the most important article is one on the genus *Ephedra*, which Mr. Miers considers has been improperly placed among gymnosperms, maintaining that it has neither naked ovules nor naked seeds, and believing that it is more allied to *Urticaceæ* than to *Cycadaceæ* or *Coniferæ*, presenting a far higher order of structure than these latter orders. The third volume, devoted entirely to *Menispermaceæ*, is promised shortly. A. W. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Life in the Deep Sea

THE interest which attaches to every fact which bears upon the phenomena of life at great depths in the ocean, will, I hope, excuse me for especially directing the attention of the readers of NATURE to the "Beiträge zur Plastiden Theorie" (published in the fifth volume of the *Jenaische Zeitschrift*), with a separate copy of which my friend Prof. Haeckel has just favoured me.

The longest of the papers which constitute the "Beiträge," is devoted to a careful study of *Bathybius*, and the associated Coccoliths and Coccospheres; and it is a matter of great satisfaction to me that Prof. Haeckel has arrived at conclusions which, in all the main points, agree with my own respecting these remarkable organisms.

In a second paper Prof. Haeckel describes a wonderful Radiolarian, *Myxobrachia*, observed during his stay at the Canary Islands, the further study of which promises to throw a new light upon the nature of the Coccoliths and Coccospheres; inasmuch as bodies of the same character were found accumulated, and apparently developed, in masses at the extremities of certain prolongations of the protoplasm of *Myxobrachia*. As *Myxobrachia* attains a length of half an inch, and seems to be abundant in the harbour of Lanzerote, it is to be hoped that Prof. Haeckel, and other naturalists, will not long remain deprived of the opportunity of submitting it to re-examination.

Another important discovery made public in the "Beiträge," is the existence of starch in the well-known "yellow cells" of the *Radiolaria*. In connection with this fact, it is interesting to remark that all the *Radiolaria* are floating organisms, and, consequently, that they are fully exposed to the light of the sun.

T. H. HUXLEY

Jermyn Street, June 23

The "English Cyclopædia"

YOUR issue of June 2 contains a long letter from "Nemo," to which a short reply seems desirable. Most of his statements are incorrect, and, as an illustration of the trustworthiness of his facts, or supposed facts, allusion may be made to his remark that all he can find in the Cyclopædia about *Arvicolæ*, *Crociduræ*, *Crossopi*, *Hypudæi*, and *Sorices* is that *Hypudæus* is sometimes spelt *Hipudæus*; whereas all the species mentioned in the Close Time Report to which he refers are described or noticed in the Cyclopædia. The species of the sub-genera *Crocidura* and *Crossopus* are referred to under their generic heading *Sorex* in the article *Sorecidæ*, E. C. Some of the terms which he says are omitted properly belong to another division of the Cyclopædia. Thus *Acclimatisation* is noticed in the Arts and Sciences division, and something additional will probably be given in the supplement to that division. Again, *Deep Sea Dredging* had scarcely become a subject of general interest when the Natural History Supplement was being written, while the character of the principal results, and the probability of great additions to the subject, rendered it advisable, as was thought, to postpone its consideration until the Arts and Sciences division was supplemented. Some of the results are, however, given under *Alcyonaria* and elsewhere in the Natural History Supplement. As regards the other subjects said to be omitted, most of them do occur. *Darwinism* is noticed under *Species*, E. C. S., and also under *Palæontology*, *Crustacea*, &c. *Dimorphism in Animals* will be found under *Annelida*, *Hydrozoa*, *Generations* (*Alternation of*), *Crustacea*, &c., in E. C. S. *Eophyton* is noticed; and *Eozoon* is repeatedly mentioned, while its systematic position is described under *Foraminifera*. The article *Entophyta* in E. C. is devoted to the fungi connected with skin diseases, while those which are associated with ague and other diseases would be most appropriately noticed in connection with those diseases, which do not belong to the Natural History division. A whole column is given to *Hyalonema* under *Alcyonaria*, E. C. S., in which the contradictory views of Drs. Bowerbank, Gray, Wright, and others, are distinctly referred to. Something is said about *Hybridity* under *Primula*. *Ornithoscelida* is not in; the term was first proposed in a paper read Nov. 24, 1869, which paper was not published in the printed form until after the Supplement had been finished. The general views on *Protoplasm* are given under *Cells*, *Amœba*, and so far as it is identical with Sarcode under *Actinophrys*, *Sarcode*, and other headings in E.C.S. *Rhizocrinus* is referred to under *London Clay*, and its occurrence in the living state mentioned. *Aerolites*: The latest reference is said to be 1861, implying, as it seems, that none of the information is of later date. Falls subsequent to 1861 are mentioned, and many of the facts are of later date; as, for example, those relating to the Alais and Orgeuil aerolites; Sorby's conclusions published in 1865; and Daubrée's experiments, of which accounts were given in 1866 and 1868. The article itself appeared early in 1869. As to the bibliography, the principal authors are mentioned, and a list of the works consulted was written, but was inadvertently omitted. It is also said that the latest reference under *Alca* is 1861, but this again is not correct. The writer of the article *Annelida* was not aware of Claparède's strictures at the time he wrote it; but, after all, they do not seem to affect materially the general statements given in the supplementary volume. Prof. Huxley's views respecting the systematic position of *Archæopteryx* are given under *Birds*, E.C.S. No reference is made to *Protagon* under *Blood*, E.C.S., nor is mention made of Day's colour tests, nor Dr. Richardson's renunciation. Of the last, all that was found in the Reports of the British Association is the title of his paper, which runs thus, "On Coagulation of the Blood; a correction of the Ammonia theory," and of which nothing more is said. Hence it was thought best to say nothing about the matter. Of the long string of terms which "Nemo" has culled from Prof. Huxley's last address to the Geological Society, and which are said to be omitted, the majority are given in the Supplement. For instance, to cite one or two cases: *Anthracosaurus* occurs under *Carboniferous* system, E.C.S.; *Evolution* under *Palæontology*; *Microlestes* under *Rhætic Beds*; and so on. As to the other remarks which have not been specially alluded to, it may be admitted that some of the articles might have been improved. *Foraminifera* would have been all the better if Haeckel's volume had been consulted, only Haeckel's work could not be got. It would have been very desirable if subjects which have been omitted had been inserted, and if cross references had been more numerous; but there were restrictions as to space which rendered it necessary to make a selection. Thus, *Meloe* was inserted and *Sphegidæ* rejected, because there was no room for both. What a Cyclopædia ought or ought not to contain is an open question. It cannot give information upon everything; and probably very few persons not specially interested in the subject want to know about *Hyænictis* or *Ictitherium*. If regard was had to the theoretical view of the matter, and not to the cost and other practical drawbacks, a full account of all that has been done in the last sixteen years would fill several volumes as large as the Supplement to the "Natural History Division of the English Cyclopædia." I beg to sign myself

THE EDITOR

Cuckows' Eggs

WHAT is the drift of this discussion on the eggs of the cuckow? Is it "natural selection," "mimetic analogy," or what? Are we to understand that by some process of "natural selection" the European cuckow can change the appearance of her egg to that of the selected foster parent? or that one set of cuckows lays eggs like titlarks, let us say, another like hedge-sparrows, and so on; and always select each its particular nest in which to deposit its particular coloured egg?

If this is it, *cui bono?* Of course to deceive the foster parent. Is this needed? I doubt it. I do not think the foster parent cares what coloured eggs she sits on, so long as they are about the size of her own, so as not to inconvenience her.

Let us see what cuckows do in other countries, and let me select Africa as my field. If deception is necessary in one country, why not in another? Le Vaillant is so inaccurate that one must take all his statements *cum grano*, but he is right in some things, where, I suppose, he had no temptation to go wrong. He says of *Cuculus gularis* "that its egg is olive grey, dotted with red" (gris olivacé, piqueté de rouge), and that it is laid in the nests of—1, the Jean Frédérick (*Bessonornis phœnicurus*); 2, Coryphée (*Bradypterus coriphæus*); 3, Traquet-patre (*Pratincola pastor*); 4, Pie-grièche fiscal (*Lanius collaris*); and 5, Bacbakiri (*Telophonus bacbakiri*). Now the eggs of No. 1 are of a dirty white or buff ground, more or less spotted with pale rufous; 2, a lovely verditer, irregularly blotched with brown; 3, also verditer, indistinctly clouded with brown; 4, pale grey, blotched at the obtuse end with greenish and reddish spots; 5, light blue, profusely spotted with brown.

Cuculus solitarius, he says, lays its pink egg, dotted with clear brown spots, in the nests of—1, *Bessonornis phœnicurus*; 2, *Bradypterus coriphæus*; 3, Le Capocier (*Drymoica capensis*); 4, Le Réclameur (*Bessonornis vociferans*); and 5, Le fauvette à tête rousse. The eggs of the last two I do not know; those of the first two are described above; those of No. 3 are blue, with brown blotches.

Oxylophus edolius and *O. melanoleucus* he confounds together, but it matters little, as the eggs are alike—pure white—and deposited in nests of—1, Bergeronette brun (*Motacilla capensis*); 2, *B. coryphæus*; 3, Gobemouche mantelé (*Tchitrea cyanomelas*); and others, whose eggs I do not know. Of 1, the eggs are greyish white, or rather nankin, minutely freckled with brown; of 3, they are cream-coloured, profusely spotted with red, brown, and purple spots, in a band at the obtuse end. One of my correspondents finds eggs of *O. edolius* in the nests of *Pycnonotus capensis*, whose eggs are rather deep lake, profusely spotted with dark markings! They also, I know, lay in the nests of *Pycnonotus nigricans*—eggs as of the last. I found Mud-birds (*Malacircus bengalensis*) in Ceylon, feeding a young *O. melanoleucos*, and their eggs are of a uniform deep verditer.

Chalcites auratus lays white eggs also, and some of my correspondents have sent what I *believe* to be their eggs taken from the nests of *Hyphantornis capitalis*, whose eggs are green, profusely speckled with brown, and dark salmon-colour profusely speckled and spotted with dark brown and black.

Now, will any one say, after comparing these different cuckows' eggs with those of the nests in which they have been found, that there is any attempt at imitation, and if not in so many cases, why in that of *C. canorus?*

I used to think and so I wrote ("Birds of South Africa," p. 252) that the eggs of parasitic birds "usually resembled those of the foster parent." This was my idea founded on statements concerning the European cuckow taken from books; but a valued correspondent, taking exception to my position, set me to investigate the subject for myself, and to collect together and analyse my own observations and those of my collectors in this country. She writes as follows:—"The eggs of all the cuckows that I have met with in this country (South Africa) are white, and moreover they are nearly always larger than the eggs of the bird in whose nest they are deposited. With regard to distinguishing eggs, birds of all kinds are exceedingly short-sighted. We used to amuse ourselves by changing the eggs in all the birds' nests we knew of. The owners seldom left them, but took to the strange eggs; and unless their habits were remarkably different, they would blindly rear each other's young, just as they do the young cuckows. It is not necessary, therefore, for nature to make this provision. My second son once filled a Cape canary's nest with so many eggs that when the young were hatched they were more than the poor birds could manage to provide for, and having repented of his mischief, he was obliged to help them bring up their young." (Cf. *Ibis*, 1868, p. 247.)

Since this was written, I have had the advantage of visiting my correspondent, who is well known throughout this colony for her talents, love of natural history, and powers of observation. We often discussed this subject. She and her sons assured me they never cared to select eggs like those of the foster-parent, but simply eggs of those whose food they knew to be similar. They said the confusion they caused was most amusing, but only after the young were hatched. The eggs were incubated without any demur on the part of the foster-mother. After this, surely I may ask *cui bono* the *C. canorus* imitation?

E. L. LAYARD

Cape Town, Cape of Good Hope, May 3

The Chromatic Octave

I HAVE to thank "M. A." for his letter in NATURE of June 9th, suggesting that the wave-frequency to which the complementary of any tint is due, may be, not the geometric mean between that tint and its octave, as I suggested in a letter in NATURE of 28th April, but the harmonic mean. I can scarcely doubt that there must be some simple arithmetical relation between the wave frequencies of any tint and its complementary, but I see no *à priori* reason for expecting to find one such law rather than another; we must try which assumed law will most nearly coincide with fact, and the hypothesis of a harmonic mean does so coincide pretty nearly. The following table (see my previous letter) gives the ratios of the wave-frequencies of red, orange, and yellow as observed, of their complementaries as observed, and of the same as calculated on the hypothesis of the harmonic mean:—

			Observed.	*Calculated.*
Red	36·40	Bluish Green	48·30	48·53
Orange	39·80	Blue	51·80	53·07
Yellow	41·40	Indigo	54·70	55·20

The discrepancies between the observed and the calculated outlines are much less on this hypothesis than in that of the geometric mean; but they are on the same side, and, as I explained in my former letter, I think it likely they may be due to the solar spectrum not being of a truly white colour, owing to the absorption lines toward the violet end. They are on the side which this way of accounting for the fact requires. It would be desirable to make a set of comparative experiments with solar light and the electric light, as I suggested before, in order to clear up this question.

Old Forge, Dunmurry, Co. Antrim, June 13 — JOSEPH JOHN MURPHY

On the reported Current in the Suez Canal

IT is stated on excellent authority that a constant current runs through the central portion of the Suez Canal, from the side of the Mediterranean to that of the Red Sea, and a good deal of surprise has been excited by this apparently anomalous phenomenon. A little consideration will, however, suffice to establish a theory, that constant currents are almost necessary conditions of inter-oceanic canals, and that their absence, not their presence, would be contrary to just expectation. My reason is based on the improbability that a long canal, A B, could be constructed across strata that are almost necessarily inclined in one direction more than another, which should not resist the flow of tidal water from, say, A towards B, more than from B towards A. Wherever this differential aspect is established, a quasi-valvular action is called into existence, and a current along the middle of the canal, in a constant direction, is the necessary consequence.

Let A B be the canal, and *a b* the extreme limits of tidal influence. After each successive rise and fall of the tide on either side, more water will have passed from A towards *a*, than

will have returned from the side of *a* to A, and more water will be able to travel from the side of *b* to B, than can get up the canal from B towards *b*. Consequently there will be a constant current in the ultra-tidal portion, *a b*, of the canal, from the side of A to that of B.

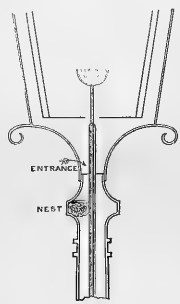
I have made some inquiries, but am unable to learn what notchings, indentations, or sweeps of the sides of a canal, would exercise the greatest differential effect, at low velocities, of the kind of which I am speaking. However, I hear it is a fact well known to sailors, that a spar cannot be towed behind a boat, unless with the greatest difficulty, if its small end be foremost, whereas, it is moved easily enough if its thick end be in front. I argue from this that if a number of spars were moored against the sides of the canal, with their large ends towards A, much less strain would be exerted on the ropes by which they were secured when the current ran from A to B, than when it ran from B to A, and consequently that the current itself would be much less resisted in the former than in the latter case. A succession of very long notches in the sides of the canal would produce identically the same effect, and might call into existence a considerable aggregate of differential resistances. I constructed a model for the purpose of experiment, but found it much too small to give satisfactory results; nevertheless, I will describe it, in hopes it may save trouble to others in designing a suitable arrangement, for the same purpose, on a larger scale. A notched trough was cut, running up and down in long zigzags, and its two ends were brought together into the same reservoir. By alternately allowing water to run into the reservoir, and then drawing it off, the effect of the rise and fall of the tide was simulated. I scattered lycopodium on the water, in the middle part of the channel, to show the direction of the current.

I venture to suggest to those engineers who are connected with inter-oceanic canals, the importance of making experiments on this problem, because it may prove to be quite within their means to produce and to regulate a current within such canals, in the direction and of a velocity most convenient to keep its bed clean and serviceable. FRANCIS GALTON

Birds' Nests

BIRDS, though almost always adapting themselves to circumstances in the use of materials, are frequently, even in the country, very eccentric in their choice of a place for their nests. I have seen a blackcap's nest built of the ordinary materials, in an open flower-pot standing on the top of a garden wall. Apparently there was no possible reason for this, there being plenty of hedges and banks hard by. But in the neighbourhood of London birds may be allowed an excuse for their eccentricities.

In a quiet street in one of the southern suburbs there is now a pair of tom-tits who have taken possession of a cast-iron lamp pillar, wherein they have built their nest and reared their young for two or three years past. It is curious to think what business they could have had there, to have found out that it was a suitable residence. The nest is placed in the bulb or swelling out of the column, just below the lamp, and the birds creep through



the space between the gas-pipe and the iron rim at the top of the column. This space is not three-quarters of an inch in width. The nest is on one side of the pipe, and cannot be more than two inches across. The lamp is lighted every evening, and on one occasion the pillar was actually taken down for some repairs with the nest inside, containing seven or eight eggs, which were, I believe, destroyed; but the birds, concluding I suppose that this was not done with *malice prepense*, but that it was only a necessary domestic difficulty, wisely returned to their home, and continued to occupy the lamp pillar for the remainder of the season, rearing another brood that same year. The accompanying sketch shows the position of the nest. Under the eaves of the adjacent house, two pairs of house martins have built this year. They came flitting about on the 1st June, and the weather being very dry, and no mud to be got at, the "gudeman" of the house kept a little spot in the road well watered, from whence the birds obtained all their necessary mud. The sparrows would plump down after the martins, thinking there was food there, and stand watching the martins at this little wet spot, and wondering apparently why they kept on flying down here, where there was no grub to be got. They tried hard to obtain possession of the martin's nests when half built, but were constantly driven away by the gentleman of the house, and now the nests are finished, and the entrance too small for the sparrows to get in; so that they dwell in comparative security. Two of these martins seem to be the sole occupants of their nest, but the other nest appears to be visited, at least, if not owned by, more than one pair of birds, three or four birds being often seen there at one time. I have often noticed this in the country, but never saw any remarks about it recorded by any one.

C. W. W.

"Other Worlds than Ours"

MR. PRITCHARD, in reviewing my book on the plurality of worlds, says that I represent Mr. Lockyer as impeding the progress of science; on the contrary, I regard Mr. Lockyer as one who has, in a most marked and important manner, advanced the cause of science, and I confidently anticipate admirable work from him in the future. It is surely not wrong in me to express openly my opinion that Mr. Lockyer's theory of the corona * is erroneous, or that (precisely *because* an expedition will set forth next December to observe the corona) the arguments against it cannot advantageously be neglected. But to assert, in the face of the fact that I give *reasons* for objecting to it, that I object "simply because" Mr. Lockyer's "opinions do not square with mine," is to make a misstatement which one can scarcely imagine to result from mere negligence.

Mr. Pritchard quotes my words, "I have very little doubt that Uranus has at least eight satellites," and asks how I venture to set my *opinion* in antagonism with Mr. Lassell's *observations.* How strange he should not have quoted the next sentence also, which would have shown that, as a matter of fact, I set the *observations* of Sir W. Herschel against the *opinion* of the esteemed and eminent astronomer who is President of the Astronomical Society. One can scarcely imagine this omission to result from mere negligence.

Mr. Pritchard makes me say, in the face of Sir William Thomson's abandonment of the theory, that the sun's heat is derived from a battery of meteors, "*I am quite certain* . . . that at least an important proportion of the sun's heat" is so supplied. And he adds, "We may fairly ask whence has Mr. Proctor this *certain* knowledge?" How strange that he should have omitted the remainder of the sentence! What I actually wrote was, "I am quite certain there is no flaw in the evidence I have adduced from the laws of probability, and that we are bound to accept as a legitimate conclusion from that evidence the theory that at least an important proportion," &c. This reference to the evidence, and to the laws of probability, would have spoiled Professor Pritchard's reasoning. Here, again, we can scarcely imagine that the omission results from mere negligence.

There are other points of the same kind in Mr. Pritchard's review, which space prevents my dwelling on. Suffice it to say, that *every criticism it contains* is vitiated by misstatements or omissions, which one can scarcely imagine to result from mere negligence.

RICHARD A. PROCTOR

Pinkish Colour of the Sun

IN reference to the "pinkish colour of the sun," noticed by several of your correspondents, it may interest them to learn that in one of the last numbers of *Cosmos* an account is given of this very same appearance, observed on the 23rd of May, at Rohrbach, on the Moselle, by a M. Hamant. He states, "that up to about two o'clock the day had been very warm, without a breath of wind. At twenty minutes past two the horizon became charged with mist, and a storm seemed imminent. About three the sun lost its brilliancy, assumed a pale yellow hue, and might have been taken for the moon had it not been for its diameter. The mist now began to rise, a north-west wind began to blow very hard; at half-past four the sun became rose-coloured, and at a quarter-past five it turned scarlet."

The exact coincidence to be observed between this account and that given by Mr. A. S. Herschel (NATURE, June 16), is worthy of notice.

Mr. Herschel similarly observed this "very unusual pinkish colour," between five o'clock on the 23rd of May, at Hawkhurst in Kent. He notices the "thick haze of apparently low cirrostratus or, perhaps, rain cloud." This phenomenon is so rare that it is mentioned in old chronicles as a sign of Divine wrath. Of late years the most remarkable case was that observed in South America by M. Emdiais, alluded to in *Cosmos.*

It is, however, especially to be noticed that whereas the two accounts referred to above state distinctly that the phenomenon occurred on "the 23rd of May," your other corespondents state that it also occurred "on Sunday, the 22nd," at about the same time, five o'clock. (See NATURE, May 26, June 2).

It is most remarkable that such a rare phenomenon should have occurred on two consecutive days; visible on the first day at Dunmurry and Dublin and Tynemouth, and on the second in Kent and Gloucestershire and on the Moselle. The hazy nature of the atmosphere on both days seems to have been permanent, and is, without doubt, the cause of the phenomenon.

Merton College, Oxford, June 28

Monographs of M. Michel Chasles

A FEW years ago I read ten or a dozen papers of a masterly history of geometry by M. Chasles. It was in French, in some quarto transactions of a learned society.

I am desirous of recovering the title and reference, and ask for assistance in the columns of NATURE.

No such a paper as that I refer to is in the Royal Society's admirable catalogue.

Was Chasles' *Aperçu historique* contributed to a learned society? It was published at Brussels, in 1837, but it is scarce, and I have not seen a copy.

Ilford, E., June 11

Geographical Prizes

IN reading the report in a recent number on the Prize Medals of the Royal Geographical Society, doubtless many of your readers will have thought very reasonable the wish of Sir Roderick Murchison, "that Eton, Harrow, and Rugby, and other great schools might in future years send candidates for these medals."

It may be well therefore if I explain very briefly the grounds on which the masters of Rugby were almost unanimous in wishing to decline the invitation of the Royal Geographical Society.

The examination is in fact a competition between schools in a subordinate branch of education. Hence the advantage lies not with the best school, but with the one which allows the greatest liberty of choice of special studies. A school like Rugby, whose curriculum, though not narrow, is strongly defined, is at a positive disadvantage in such a competition with a school whose general curriculum is narrower, but its organisation looser; one which allows free specialisation, and prepares for particular examinations. We cannot feel that the school that wins is likely to be the best school.

Further, we agreed that the proposal would not really encourage the study of geography in the school, but would attract only a few individuals. There are in every school certain accumulative prize-acquisitive boys who would learn Chinese or Crystallography or Indian Finance if a prize were offered for such subjects; and it would be these boys who would compete for the geographical medals—such boys would gain little by learning, and the school would gain nothing.

On these and some other grounds the proposal was declined by the Rugby masters; and when it is recollected that it was when Dr. Temple was head-master, most of your readers will be sure that it was not from indifference to real progress, nor from stupidity, nor from fear of novelty, nor to avoid honourable competition with other schools, that we did so decline it.

Rugby, June 13 J. M. WILSON

* For an accurate though incomplete statement of Dr. Frankland's and Mr. Lockyer's theory of the Corona, we refer our readers to the first number of NATURE Many of them will not be surprised to find that it is *not* what Mr. Proctor states it to be. Dr. Frankland and Mr. Lockyer, from their laboratory experiments, have shown that the pressure at the base of the chromosphere is small, and they have therefore stated that it is scarcely possible that a very extensive atmosphere lies outside the chromosphere. Mr. Lockyer has shown, moreover, that the height of the chromosphere as seen by the new method probably falls far short of its real height as seen during an eclipse as it was seen by Dr. Gould. A reference to the same number of this journal will also show that Mr. Proctor has misrepresented Dr. Gould's statements, which endorse the idea put forward by Dr. Frankland and Mr. Lockyer. Dr. Gould has expressly stated "that there were many phenomena which would almost lead to the belief that it was an atmospheric rather than a cosmical phenomenon." This is an opinion held by Faye and other distinguished astronomers, and Mr. Lockyer has simply shown that should this turn out to be the case, the continuous spectrum observed may be explained. Astronomers did not require Mr. Proctor to tell them what he has recently been enforcing; but, more modest than he, they have been waiting for facts, and Mr. Proctor surely is old enough to see that by attempting to evolve the secrets o the universe, about which the workers speak doubtfully, out of the depths of his moral consciousness, he simply makes himself ridiculous, and spoil much of the good work he is doing in popularising the science.—ED.

NOTES

It is with very great pleasure we state that an English friend has just received a letter from Baron Liebig, in his own handwriting, dated Munich, the 1st inst. Although still very weak, he is now able to get into his garden for some little time daily. If he continues to progress as he is now doing he proposes going to Switzerland, to the Engadine, in three weeks, where it is hoped he may soon become quite strong.

Death has been busy lately among the more eminent members of the medical profession. We have this week to record the decease of Sir James Clark, Bart., M.D., F.R.S., chief physician to Her Majesty, which took place on the 29th ult., in the 82nd year of his age. Sir James had held the appointment of physician to several members of the Royal Family, was the author of several works on climate and on consumption, and was a member of the Senate of the University of London. He attended the poet, John Keats, during his last illness at Rome in 1821.

The Radcliffe Observer at Oxford, the Rev. R. Main, has just issued a second Radcliffe catalogue, containing 2,386 stars deduced from observations extending from 1854 to 1861. The well-known care taken by the observer in the reduction of observations, and the admirable instruments in the observatory under his charge, render this volume a very valuable addition to our astronomical libraries.

We have received from Mr. Van Voorst a most beautiful book, which every scientific man in this and other lands will be glad to possess. Its contents are sixteen portraits of eminent scientific men, photographed by Dr. Wallich, the well-known naturalist, and with a skill quite unsurpassed, so far as we know, in any previous attempts. Dr. Wallich states that his aim has been to supply likenesses that shall be both characteristic, free from some errors in taste but too frequently manifest in photographic portraiture, and trustworthy as records of individual feature and expression; and in all these points the likenesses are admirable. We could hope that the success of this volume would be such as to induce Dr. Wallich to enlarge his scientific series. We may add that the present portraits are those of General Sir E. Sabine, Sir R. I. Murchison, Profs. Owen, Bentham, Huxley, Tyndall, Stokes, Ramsay, and Williamson, Dr. Hooker, Sir C. Lyell, Sir W. Logan, Viscount Walden, the Rev. G. B. Reade, and Messrs. Lassell and Prestwich.

At the meeting of the French Academy of Sciences on the 27th ult. the section of Anatomy and Zoology presented the following list of candidates for the place of correspondent vacant by the death of Prof. Carus. In the first rank, Prof. Brandt of St. Petersburg; in the second rank and in alphabetical order MM. Bischoff (Munich), Darwin, Huxley, Hyrtl (Vienna), Leuckart (Leipzig), Lovén (Stockholm), Steenstrup (Copenhagen), and Vogt (Geneva). The election was to take place on Monday last.

A Committee of the House of Commons having reported in favour of the establishment of the national natural history museums on the Thames Embankment, Mr. Beresford Hope inquired, on Monday evening last, whether it was the intention of the Government to carry out this recommendation. The Chancellor of the Exchequer replied that such an appropriation would deprive the ratepayers of a large portion of the land which was to be laid out as public gardens, and therefore Her Majesty's Government were not prepared to ask Parliament to carry out the recommendations of the committee. We are very glad to hear that the Government does intend to insist on so large a portion of the Embankment being rescued from the builders. But have the interests of the ratepayers been so jealously guarded when other claims than those of science were placed in competition with them?

At the D.Sc. examination of the University of London, just held, candidates passed in the following branches:—Branch I.—Mathematics, John Hopkinson, Trinity College, Cambridge, and Owens. Branch IV.—Inorganic and Organic Chemistry or Mineralogy: James Bottomley, B.A., Owens College; David Watson, Royal School of Mines; John Watts, private study. Branch V.—Organic and Inorganic Chemistry: James Campbell Brown, Royal College of Chemistry and private study; Charles Romley Alder Wright, Owens College. Branch VIII.—Physical Optics; Heat; Acoustics: John Hopkinson, Trinity College, Cambridge, and Owens. The D.Sc. examination is intended by the University to be the highest possible test of proficiency in some one particular branch of science, and can be taken in any one of sixteen different branches. It is encouraging to find that not only have a larger number passed the examination than in any previous year, but that it has been taken in branches in which there has hitherto been no candidate; and moreover, that one gentleman has passed in two distinct branches. Owens College may well be proud of the number of successful candidates it has sent up.

At a meeting of the Council of the Royal School of Mines, held on Saturday, July 2nd, the following awards were made:—Two Royal Scholarships of 15*l.* each for first year's students, to W. H. Greenwood and F. C. Milford; H.R.H. the Duke of Cornwall's Scholarship to P. C. Gillchrist; the Royal Scholarship of 25*l.* to R. R. Atkinson; the De la Beche medal and prize of books to W. Gowland; and the Director's medal and prize of books to P. C. Gillchrist. The Edward Forbes medal and prize of books were not competed for this year. The title of Associate of the Royal School of Mines was conferred upon the undermentioned gentlemen:—In the Division of Mining—Messrs. William Gowland, Archibald Liversidge, and H. J. Renwicke. In the Division of Metallurgy—William Gowland, Dillon, Liversidge, A. W. Bickerton, F. W. Bayley, and T. Jones. In the Division of Geology—W. Johnson Sollas.

The examination for women above eighteen years of age, conducted by the University of Cambridge, has been proceeding during the present week, at three centres, London, Manchester, and Rugby. The number of entries last year was thirty-six, this year they have increased to eighty-four, and we are glad to observe that there are candidates in several branches of natural science which were not touched last year, among them Zoology, Botany, and some of the higher branches of Mathematics.

The *Athenæum* states that the University of Vienna has decided to admit women to all the advantages of its medical school, and that two French students have already availed themselves of the privilege.

A telegram from Athens speaks of an earthquake which has taken place in the island of Santorin. The town is a mass of ruins, and several small islets have been submerged.

Dr. Petermann announces in the *Cologne Gazette* that the *Warag*, one of the best steamers of the Russian fleet, left Helsingfors on the 7th of June, under the command of Captain Krämer, on a scientific expedition to Nova Zembla and Spitzbergen. The *Warag* is to proceed *viâ* Bergen, Hammerfest, and Vardö. It will be accompanied by two or three steamers from Archangel, with the Grand-duke Alexis and several eminent scientific men on board. This expedition is to be the precursor to a more important one which is being prepared by the Russian Geographical Society, and will proceed next year to the North Pole.

THE *Moniteur Scientifique* for June 15th, edited by Dr. Quesneville, contains three articles taken from our columns, the source of two only of which are acknowledged—"The Science of Explosives applied to the Art of War," and "Scientific Experimental Research," by Mr. George Gore (or, as the French rendering has it, Mr. George Core). The third, Dr. Lankester's article on "The Extract of Meat," appears as an original paper.

THE annual meeting of the Royal Archæological Institute of Great Britain and Ireland will be held at Leicester at the end of the present month. The meeting is under the patronage of Her Majesty and the Prince of Wales, and Lord Talbot de Malahide, F.S.A., is the president of the year. Leicester itself possesses many features of archæological interest. These include its mediæval churches, the Norman hall of its ancient castle, the "newarke" of the castle, numerous Roman pavements, one being *in situ*, and the noted mass of Roman masonry called the "Jewry Wall," the ancient hall of Corpus Christi Guild, the Chapel of Trinity Hospital, and the now forsaken hospital of William de Wyggelston. With these may be mentioned the site of Leicester Abbey, surrounded by its original walls, where Cardinal Wolsey breathed his last. Among the features of interest which will be included in the proceedings of the week will be the inspection of Kirby, Muxloe Castle, Ashby-de-la-Zouch Castle, the ruins in Bradgate Park, so intimately connected with Lady Jane Grey, the remains of Ulverscroft Priory, the curious stained glass of Woodhouse Chapel, the house known as Latimer's at Thurcaston, the noble church at Melton Mowbray, the fine Norman hall at Oakham, the interesting hall and church at Exton, and the remarkable encampment at Barrow-on-the-Hill. A temporary museum will be established as usual during the week, and will include a collection of portraits of worthies connected with the counties of Leicester and Rutland.

THE general monthly meeting of the Royal Institution of Great Britain was held on Monday, July 4, Sir R. I. Murchison, K.C.B., F.R.S., in the chair. The secretary announced the receipt of 2,000*l.*, a legacy from the late Mr. Alfred Davis, M.R.I., for the promotion of experimental researches.

BABOO RADANAUTH SICKDAR, for many years chief computer to the Trigonometrical Survey of India, at one time in charge of the Calcutta Observatory, and a mathematician of some attainments, died in May last at Calcutta.

THE Governor of Madras has presented to the Horticultural Gardens there four young date palms, which he has procured from Egypt.

THERE has been for some time in India a discussion on the subject of pearl oyster banks on the Tinnevelly coast. Those who have maintained the existence of the oysters are now fully confirmed by the discovery of young oysters in abundance. One bank is four miles in length and about two in width, and in another two years will yield a good harvest of pearls.

A MINERAL spring has been discovered in the Gheiveh hills, near Broussa, in Asia Minor.

THE foundation-stone of a new Observatory was laid at Port Louis, Mauritius, on the 30th of May, by H.R.H. the Duke of Edinburgh, to be called the Royal Alfred Observatory. In addition to astronomical observations, it is intended to make the Observatory a centre for researches for the advancement of meteorology and terrestrial magnetism. Full particulars of the ceremony will be found in another column. In Sir Henry Barkly, who is about to leave Mauritius for the Cape, the colony will lose a Governor who has always had at heart the promotion of everything connected with physical and natural science.

THE temperature of the Cranial Cavity has lately been investigated by Mendel, of Pankow near Berlin. He states that Fick had already found the normal temperature of the cranial cavity to be lower than that of the body generally. Jacobson and Bernhardt had similarly noticed the inferior temperature of the blood arriving at the heart by the superior vena cava, and the depression produced by it in the right cavities. M. Mendel corroborates these results, and finds constantly that in health there is a difference of from seven-tenths to one degree centigrade between the temperature of the cranial cavity and the rectum in the rabbit, and that in the dog the difference is almost as well marked. Duméril and Demarquay have shown that the temperature of the body is lowered by the action of chloroform. Bouisson arrived at the same results, as have also Sulzynski and Scheinnesson; the latter experimenting upon man. The difference observed by Mendel between the cranial and rectal temperature is much more pronounced when the animal is under the influence of chloroform than when in health. Chloroform lowers the temperature generally, but especially that of the cranial cavity. The effects produced by chloral on the general temperature have been already studied by Demarquay. This author has found that the temperature of the body falls several tenths of a degree. Mendel arrives at the same results in regard to the temperature of the cranial cavity, except that it falls to a still greater degree than the general temperature. Dequix, Dupuy, Leuret, and Gscheidlen have found that after a medicinal dose of morphia the temperature of the body rises, though when given in a poisonous dose it falls. Mendel again arrives at a similar conclusion, viz., that the depression of temperature is more rapid and more marked in the cranial cavity than in the rest of the body. In poisoning by alcohol the temperature of the cranial cavity rises to such a point that it surpasses the temperature of the rectum.

THE hygrometrical balance compensating for the severe drought under which Western Europe has been suffering for the past three months, appears to have been maintained by an unusually heavy rainfall, reported at the Paris Observatory as having been experienced in Egypt, Lybia, Asia Minor, and Russia. The Paris correspondent of the *Daily News* states that two theories to account for the drought have been broached among French *savants*. One of these attributes to the cutting of the Suez Canal a displacement of the atmospheric currents which regulate the weather of Europe and North Africa! The other theory is grounded on the statement that the spring rains in France are caused by atmospheric commotions resulting from the breaking up of the ice fields to the east of Newfoundland, and that for this reason a long and severe winter in the Arctic regions is followed by a dry spring and severe and destructive summer storms in Central and Western Europe. The author of this theory suggests that science should be employed in breaking up the ice-fields at the end of a severe winter by nitro-glycerine and picrate of potassium. This scheme is advocated in the pages of *Cosmos*, by a civil engineer of the name of V. Prou, who proposes forming an "Insurance Company against Drought," for the purpose of assisting nature in the disintegration of the Polar ice, and thus forming a more equable temperature.

WE are glad to see that the *savants* of Haarlem continue to bring out the "Archives du Musée Teyler." The new fasciculus just received in London contains the following papers:—"Sur les insectes fossiles du calcaire lithographique de la Bavière," by H. Weyenbergh, jun.; "Description d'un crinoïde et d'un poisson du système heersien," by Dr. T. C. Winkler, and a further instalment "Sur la Dispersion," by Van der Willigen. The plates representing the fossil insects and the crinoïd are beautifully executed, and for purposes of study are almost as good as the originals. By way of explanation we mention that the "Système Heersien," takes its name from a district in the province of Limburg, in which two villages, Upper and Lower Heers, are situate.

FACTS AND REASONNIGS CONCERNING THE HETEROGENOUS EVOLUTION OF LIVING THINGS *

II.

A.—*Experiments in which the fluids employed were raised to a temperature of* 100° *C. for from* 10 *to* 20 *minutes before the flask was hermetically sealed.*

a. Fluids employed being filtered infusions containing organic matter in solution.

1. *Infusions either slightly alkaline or neutral.*

Experiment 1.—A flask containing filtered beef-juice *in vacuo*, which had been hermetically sealed twelve days previously, after the fluid had been boiled for 15 minutes, was opened on January 7, 1870.

The solution itself was clear, and there was no pellicle on its surface, although there was a slight flocculent deposit at the bottom of the flask. The end of the flask having been broken off and its contents shaken, the first drop which was examined with a magnifying power of about 600 diameters † showed the most unmistakeable living organisms. There were mere moving

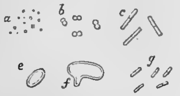

FIG. 6.—*Monads, Bacteria*, and other organisms met with in first experiment.

specks or monads (*a*); several active organisms made up of two minute sphericles (*b*); a few medium sized, actively moving bacteria (*c*); an actively moving spheroidal body $\frac{1}{10000}''$ in diameter (*d*); and several simple cellular bodies with a moderately thick cell wall, but apparently containing only fluid contents. These latter bodies varied in size from $\frac{1}{7500}''$ to $\frac{1}{3300}''$ in diameter. Most of them were simply ovoidal (*e*), one or two of them were seen to be more irregular in shape, either having projections (*f*), or even, as in one case, presenting projections something like cilia.

In the second drop of fluid examined, with the exception of a little granular matter, there were only seen several small but very active bacteria (*g*).

Experiment 2.—A flask, containing a mixed infusion (rather weak) of beef, carrot, and turnip, *in vacuo*, which had been hermetically sealed fourteen days previously, after the fluid had been boiled, was opened on December 23, 1869. The first two or three drops showed a large number of actively moving monads; a number of moving particles having an altogether irregular shape; bacteria distinct and moving, though less numerous; a number of spherical *Torula*-like cells of different sizes, containing a central dot (*a*); and a number of bodies mostly in the form of

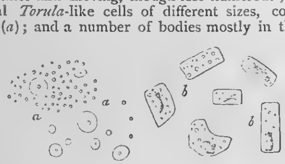

FIG. 7.—*Torulæ* and other organisms met with in second experiment.

parallelopipeds with rounded angles (*b*), though some were quite irregular in shape—these containing granules of various sizes, with sometimes large and altogether irregular protoplasmic-looking masses.

Experiment 3.—A flask containing a weak decoction of beef and carrot *in vacuo*, which had been hermetically sealed thirty-nine days before, after the fluid had been boiled, was opened on January 18, 1870.

This flask had been allowed to remain so long before it was opened because the fluid within showed no noticeable signs of change. There was no pellicle, and only a very small amount of granular material at the bottom of the flask.

On microscopical examination no distinct living things were found. Only a small quantity of motionless granular matter was seen.

Experiment 4.—A flask containing an infusion of hay, together with a few grains of phosphate of soda, *in vacuo*, which had been hermetically sealed seventeen days previously, after the fluid had been boiled, was opened on January 25, 1870.

The fluid itself was not turbid or cloudy, though it had become darker in colour. The bottom of the flask was irregularly lined with granular and slightly flocculent material.

On microscopical examination of two or three drops, there were seen many actively-moving monads; some bacteria of medium size; many quite irregularly-shaped particles in active movement; many flattened bits of protoplasmic-looking material with irregular and slightly curled edges, slowly moving, and ranging in size from $\frac{1}{10000}''$ to $\frac{1}{5000}''$ in diameter (other masses of this kind were distinctly hollow though mostly irregular in shape); and lastly there were several large irregular masses of fibres, the nature of which could not be determined.

2. *Infusions having an acid reaction.*

Experiment 5.—A flask containing a filtered infusion of turnip *in vacuo*, which had been hermetically sealed only *five* days previously, after the fluid had been boiled, was opened on December 15, 1869.

On the second day after the flask had been sealed, the previously clear solution began to exhibit a cloudy appearance. The next day a reticulated scum was seen on the surface of the fluid, which gradually became more manifest on the two following days. When the neck of the flask was opened, its contents were found to emit a most fœtid, sickly odour.

Microscopical examination revealed a very large number of bacteria and vibrionic-looking rods, some straight and others bent, some motionless and others exhibiting languid movements. These, mixed up with a thickly interlaced network

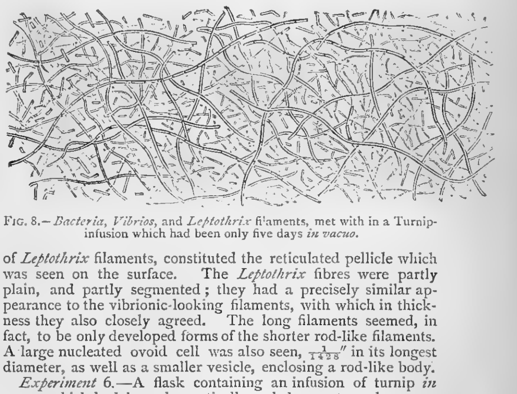

FIG. 8.—*Bacteria, Vibrios*, and *Leptothrix* filaments, met with in a Turnip-infusion which had been only five days *in vacuo*.

of *Leptothrix* filaments, constituted the reticulated pellicle which was seen on the surface. The *Leptothrix* fibres were partly plain, and partly segmented; they had a precisely similar appearance to the vibrionic-looking filaments, with which in thickness they also closely agreed. The long filaments seemed, in fact, to be only developed forms of the shorter rod-like filaments. A large nucleated ovoid cell was also seen, $\frac{1}{1428}''$ in its longest diameter, as well as a smaller vesicle, enclosing a rod-like body.

Experiment 6.—A flask containing an infusion of turnip *in vacuo*, which had been hermetically sealed seventeen days previously, after the fluid had been boiled for 20 minutes, was opened on January 25, 1870. The fluid never exhibited any distinct turbidity, and no pellicle formed on the surface; there was, however, an irregular covering of the bottom of the flask by fine granular matter, with here and there a small patch of filamentous-looking substance. No bad odour was perceived on opening the flask.

Unfortunately just as I was proceeding to examine the contents microscopically, nearly all the fluid was lost, including the filamentous-looking masses. Examination of a few drops of the fluid which remained showed a very large number of monads and bacteria; only a few of them were isolated and displayed movements; they were for the most part aggregated, either into spherical masses or else in the form of portions of a broken layer which presented traces of a *secondary organisation* similar to that represented in Fig. 1.

Experiment 7.—A flask containing an infusion of turnip *in vacuo*, which had been hermetically sealed seven days previously, after the fluid had been boiled for 20 minutes, was opened on February 4, 1870.

* Continued from p. 177.

† An objective of this power was used throughout these investigations; it was an "immersion" glass (No. 9) of Nachet's make. All the objects were drawn, therefore, as seen with a magnifying power of about 600 diameters.

The solution itself was much clouded, and its surface was covered by a thick gelatinous pellicle.

On microscopical examination of the fluid it was found to contain a multitude of very active monads and bacteria. The thick gelatinous pellicle was also made up of an aggregation of these in the usual transparent mucoid material. In very many situations this uniform pellicle was undergoing a process of *secondary organisation*, such as I have already fully described as leading to the production of unicellular organisms, and such as was seen to a less extent in the last experiment.

Experiment 8.—A flask containing a very strong infusion of turnip *in vacuo*, which had been hermetically sealed fifteen days previously, after the fluid had been boiled for 15 minutes, was opened on February 28, 1870.

The solution itself was very cloudy, and there was on its surface a thick coriaceous sort of pellicle distinguished by closely set aggregations or islets of denser growth.

On microscopical examination the fluid was found to contain a multitude of very active monads and bacteria. The bacteria were almost more active than any I had before seen, and there were many different kinds. Some exhibited rapid serpentine movements, accompanied by flexions of the two segments of which they were composed; whilst the movements of others were rapidly progressive in straight or curved lines.

The pellicle was made up mainly of simple *Leptothrix* filaments (mostly without joints or evidences of segmentation); and the thicker islets were found to be produced by a more luxuriant growth in these situations of densely interwoven filaments.

The pellicle was found to be so tough and elastic that some of it could only be mounted as a microscopical specimen after it had been compressed for an hour or two, by placing a small weight on the covering glass.

On the same day that this solution was hermetically sealed *in vacuo*, two other portions of the same infusion were treated in a different manner for the sake of comparison. One (A) was enclosed, and sealed, in a flask with ordinary air and without the infusion having been boiled; another portion (B) was boiled for fifteen minutes, and when the solution was cool, so that the flask was filled with ordinary air as before, its neck was hermetically closed by the blow-pipe flame. The third portion (C), as above mentioned, after it had been boiled for fifteen minutes was sealed up *in vacuo*.

The changes which took place were as follows. Towards the close of the *second* day, solution A became cloudy, and twenty-four hours later that in B was in a similar condition. It was not till two days later that solution C became cloudy. Afterwards, till the fifteenth day, when they were all opened, solutions A and B underwent comparatively little change, only becoming rather more opaque, though no distinct pellicle was formed on either; in solution C, however, the pellicle continued to grow thicker and more distinct throughout the whole period. When opened the reaction of all three was still found to be slightly acid. In other respects their characters were as follows:

Odour.		*Nature of Contents.*
Somewhat sickly, with smell of baked turnip.	Solution A	A multitude of monads and bacteria of medium size, all very active.
Fragrant, like that of fresh turnip.	,, B	Small monad-like granules most numerous; bacteria scarce, and movements not very active.
Decidedly fœtid...	,, C	Monads and bacteria of many kinds, whose movements were extremely active. An enormous quantity of *Leptothrix* filaments.

The results of these comparative experiments are most interesting. The changes commenced first in the unboiled solution, as might have been imagined; then, in the two boiled solutions. We find them commencing in the solution in contact with air before they did in that which was contained *in vacuo*—the reason of this being not quite so obvious. But the changes in A and B were only able to advance to a certain extent, because, apparently, the space above the fluid being already filled with air, these changes, necessitating the evolution of gases as residual products, were only able to go on so long as the increased tension occasioned did not reach such a stage as to stop these molecular rearrangements altogether. As might have been expected, the changes which took place in A were different from those which occurred in B. Those of A seemed to have been more thorough, giving rise to a much larger quantity of bacteria, and the somewhat sickly odour of this was also intermediate between the comparatively unchanged odour in A and the decidedly fœtid odour of B, in which such an enormous development of organisms had taken place. Here, then, the advantages of the vacuum seem to be most clearly shown.

After having read M. Pasteur's account, concerning the growth and development of fungoid organisms which had been placed in saline solutions,* it occurred to me that it would be a subject of much interest to determine whether any evidence could be obtained tending to show that organisms might even be evolved *de novo* in certain saline solutions. This, in fact, seemed to be a problem of very great importance; for, if otherwise suitable, the employment of such saline solutions would be attended by certain advantages. In the first place it was likely that the saline materials in solution would be far less injured by the high temperature of 100° C. than organic substances. And since, in working with a vacuum, we are able to get rid of the air altogether as a possible "germ" containing medium, so, with the view of simplifying our experiments, it becomes desirable that everything in our power should be done to diminish the number of possible pre-existing germs in the solutions employed. But this end, also, seemed likely to be best carried out by the employment of certain simple saline solutions. We should thus be able to get rid, as it were, of Buffon's "molecules organiques," which he supposed to pervade all organic matter that had been fashioned in a Living organism—and also of those ordinary organic molecules whose presence is supposed, even by M. Pouchet and other heterogenists,† to be absolutely necessary in order that "spontaneous generation" may occur. We should thus, indeed, best emerge from the circle of the organic, thus as far as possible elude the company of all those embarrassing molecules which the vitalist may choose gratuitously to endow with "vital" properties, and to regard as the chosen seat of a special "vital force," uncorrelatable with the ordinary physical forces. We may thus be best brought face to face with the problem—Whether the pre-existence of organic matter, which has been elaborated in pre-existing organisms, is, at present, absolutely necessary for the *de novo* origination of Living things; or whether, in fact, these may arise, more or less directly, by changes taking place in an aggregation of new formed molecules of an organic type, which have been themselves produced by the combination of some of the dissociated elements of the saline substances employed.

Just as nitrate of ammonia, carbonate of ammonia, free carbonic acid, and water, with a few saline substances, constitute the materials which—under the influence of the modified physical forces operating in the Living plant—are convertible into similar living vegetable protoplasm, so the problem which now presented itself was, whether under the influence of purely physical forces—acting upon solutions containing some such ingredients—re-arrangements might not be brought about amongst the elements of the substances dissolved and of the aqueous medium itself, resulting primarily in the formation of certain new complex molecules, which, secondarily, under the continued influence of similar physical forces‡, are capable of permitting the occurrence of new modes of collocation resulting in the evolution of the minutest specks of Living Matter §.

It resolved itself, in fact, into an inquiry whether Living things can now originate on the surface of our globe in that fashion after which alone (in accordance with the evolution hypothesis) they could have originated in those far remote geologic ages when Life first began to dawn upon the still heated surface of that rotating and revolving spheroid which now constitutes our planet. Before organic matter of the ordinary kind could exist organisms must have been present to produce it. Organisible compounds of a certain kind must, nevertheless, have preceded organisms. And just as chemists are now able to build up a great number of organic compounds in their laboratories, so it seems quite possible that some such mobile compounds may have been evolved by the agency of natural forces alone acting on the heated surface of the earth, at a period anterior to the

* Annales de Chimie et de Physique, 1862, p. 106

† Who at the same time that they are heterogenists, are firm believers in a special "vital" force.

‡ Those who wish to understand how incident physical forces are capable of bringing about such re-arrangement, should consult vol. i. chap. 2, of Mr. Herbert Spencer's "Principles of Biology."

§ For the genesis of Life, we need only look after the origin of such a speck of Living Matter. This is all that would be required by the greater number of the most advanced physiologists of the day. Given a mere speck of living matter less than $\frac{1}{50000}$" in diameter, and a Living thing may soon appear in the form of a *Vibrio*, a *Torula* cell, or a *Leptothrix* filament. By all such biologists the "vital" forces are held to be *molecular* forces, and such molecular forces are nought else than the resultant attributes of the particular advent of Living things.* We at present may, therefore, well wish to know, whether what is presumed to have taken place then may still take place now, since the affirmative solution of this problem would suffice to throw a halo of reflected light back through the ages, and would thus make that which is now a mere hypothesis, approximate as much as possible to the rank of one of the best established probabilities concerning the life-history of the globe on which we live.

It was with a feeble hope of throwing light upon the above-mentioned subject that I commenced the series of experiments which are now to be detailed. These were at first somewhat tentative, but the success obtained at each step emboldened me to proceed in my endeavours to obtain Living things under more and more arduous conditions. In all cases the saline substances were carefully selected; one of the first requisites being that they should, at all events, contain the four fundamental ingredients of Living things: nitrogen, carbon, hydrogen, and oxygen. Therefore it was that in almost all cases an ammoniacal salt was one of the substances used, on account of its capability of supplying nitrogen. And, with the view of keeping up a sort of uniformity, phosphate of soda was employed as the second saline ingredient in as many of the solutions as possible. This was considered quite as suitable as any other salt, and as a phosphate it presented certain advantages.† It was deemed necessary, moreover, that a certain mixture of substances should exist, in order that there might be sufficient diversity amongst the elements coexisting in the solutions. These elements being then affected differently by the play of incident physical forces upon them, under their new modes of vibration thus excited, new and altogether different mutual affinities might become dominant, after the fashion so clearly indicated by Mr. Herbert Spencer‡ in reference to other molecular re-arrangements. And these affinities *might* also be such as would tend to a colloidal rather than to a crystalloidal mode of aggregation. Concerning such probabilities, we doubtless have much to learn. Amongst saline substances, colloidal modes of aggregation seem to be favoured under certain sets of conditions, and crystalloidal modes of aggregation under certain other sets of conditions. Prof. Graham showed that this was the case with such mineral compounds as silica, the sesqui-oxides of iron, chromium, and other bodies. Then, again, this possibility of an isomeric modification is admirably exemplified by the now well-known tendency of cyanate of ammonia to become converted into the organic compound called urea. We are told in Watts's *Dictionary of Chemistry* § that after an aqueous solution of cyanate of ammonia has been prepared, the "liquid exhibits the reactions of a cyanate, but when *heated* or left to evaporate spontaneously, it is converted into urea." This would seem to show that the passage from the crystalloid to the colloid mode of molecular collocation is by no means a difficult one—that it may be brought about, in fact, by very slight determining causes.

That transitions of a reverse order may be effected from the one to the other state or mode of aggregation—and this, too, even with more complex substances—seems indicated by the fact that certain protein compounds may exist at one time in their usual colloidal state, and at another time as statical crystalline aggregates. The possibility of the assumption of the crystalline form by a certain number of these protein or colloidal substances is, indeed, now placed beyond all doubt.‖ As the most familiar instance of this I may mention the now well-known oblique rhombic *hematoidin* crystals and other crystalline forms obtainable from blood. And amongst these latter are to be included certain tetrahedral crystals discovered¶ by Reichert, in connection with the placenta of the guinea-pig, the behaviour of which to reagents rendered it certain that they were of an albuminous or protein nature.* Chlorophyll, also, has been observed in a crystalline state by M. Trécul.† In these and in many other cases which might be cited, we have, apparently, to do with some mere alteration in the arrangement of molecules, and the crystalline form is to be regarded as possible when certain isomeric modifications are brought about in substances which ordinarily are non-crystallisable. No less an authority than M. Trécul, also, tells‡ us that he has actually seen and watched a tetrahedral crystalline mass of this kind, which had been produced within the cells of the bark of the common elder (*Sambucus nigra*), gradually undergoing a modification in form at a certain part of a most startling nature. Whilst altering in shape, the part so altering was seen to become converted into a short fungoid filament which grew at the expense of the crystal. This change in form, then, could only be taken as the external sign of a much more profound molecular rearrangement taking place within the mass, whereby it was changed from a non-living albuminoid crystal into a Living and growing organism.§ In this remarkable case there must have been not only a relapse into the colloidal mode of molecular aggregation, but a secondary assumption of a still more unstable mode of collocation, by means of which the mass was gradually converted into a living embryo fungus.

It is well, then, for us to bear these facts and statements in mind, whilst we enter into the kindred though somewhat different inquiry, whether, under the influence of suitable conditions, there is any disposition for the ultimate constituents of different saline substances, existing intermixed in a state of aqueous solution, to fall into new groupings or modes of collocation of a non-saline or colloidal nature. If this can take place, we should then have a new kind of decomposition with an almost simultaneous recomposition—a re-arrangement, in fact—giving birth to substances allied to those of the protein group. And it would be only rational for us to suppose that such new-formed protein substances would be as prone to undergo change as these substances are generally found to be. If ordinary protein substances, therefore, which have been built up as parts of Living things, are capable of going through certain Life-giving changes, it would be quite possible that the differently evolved protein—that which comes into existence "spontaneously," or without the influence of pre-existing living things—may go through similar changes. The molecular constitution of these two kinds of matter may be closely allied, and wherever Life-giving changes occur, we are entitled to look upon these as actions resulting from the influence of physical forces upon material collocations whose molecular constitution is of such a nature as to render them prone to undergo current re-arrangements. A series of actions and reactions occur between such material collocations and their environment, and as a result Living things appear and grow. This tendency to undergo change is inherent in colloidal substances. As Prof. Graham told us:—"Their existence is a continual metastatis. . . . The Colloidal is, in fact, a dynamical state of matter, the crystalloid being the statical condition. The colloid possesses ENERGIA. *It may be looked upon as the probable primary source of the force appearing in the phenomena of vitality.*"

B.—Fluids employed being Solutions of Saline Substances in Distilled Water.

Experiment 9.—A flask containing a solution (neutral) of crystallised white sugar, tartrate of ammonia, phosphate of ammonia, and phosphate of soda‖ *in vacuo*, which had been hermetically sealed nine days previously, after the fluid had been boiled for 20 minutes, was opened on January 4, 1870.

atomic collocation which displays them. The speck of living matter is held to contain no newly created force—just as no one believes it to contain newly created material units. Such a germ or embryo Living thing, is only a new mode of collocation of pre-existing matter, and of pre-existing force or motion. Its properties—the "vital" phenomena which it manifests—are the results of the particular material collocation which exists, and of the "conditions" by which this is surrounded. A Living thing is a dynamic aggregate, and between such aggregate and its environment, there is continuous action and reaction so long as Life exists.

I have given the reasons for such views a little more fully in an article entitled "Protoplasm" (NATURE, Feb. 24, 1870), and I would again refer the reader to the views announced by Prof. Huxley and Prof. Tyndall (Note, p. 175).

§ M. Trécul's own words are as follows:—"Lors de mes observations en 1860, j'avais reconnu que des corpuscles colorables en violet par l'iode remplacent frequemment les tétraèdres après la putréfaction, mais je ne vis pas à cette époque la transition des uns aux autres. Je fus plus heureux cette année; j'ai vu les tétraèdres s'allonger par un de leurs angles, et passe graduellement à nos singulières plantules en produisant une tigelle cylindrique. Dans ce cas le tétraèdre, arrondi ou encore anguleux, représente la bulbe. Le tétraèdre peut même s'effacer complétement, et ne laisser après lui qu'une plantule fusiforme ou cylindrique."

‖ The several ingredients were contained in this solution in the following proportions:—To 80 parts of water there were added 16 parts of sugar, 1 part of tartrate of ammonia, and ½ a part each of phosphate of ammonia and phosphate of soda. This solution, therefore, did not contain saline substances alone; the presence of sugar made it form a connecting link, as it were, between the solutions containing organic matter only, and those in which saline substances alone were contained.

Before the flask was opened the solution itself was clear and without the least trace of a pellicle on its surface, though for the last three or four days a very fine deposit was seen on certain parts of the bottom and sides of the flask.

When examined microscopically, a very few monads and bacteria were found in the first few drops of the fluid, which had been poured out before the whole was shaken. The remainder was then poured into a conical glass, and after having been allowed to stand for a time, the supernatant fluid was removed, and the last few drops containing the sediment were examined. In this were seen many bacteroid particles (*a*) and monads of different sizes, exhibiting the most active movements, as well as some irregular-

FIG. 9.—Organisms met with in Experiment 9

shaped particles, also active. Many of the mere monad-like particles had the appearance of being very small *Torula* globules (*b*), and one cell of this kind was seen $\frac{1}{7500}''$ in diameter, and containing a nuclear particle in its interior. Many groups made up of three ovoid particles (*c*) were also seen, and also a dumb-bell-like body, all exhibiting slow movements. There were, moreover, motionless protoplasmic-looking masses—some cuboidal or more or less spherical and hollow, and others altogether irregular in shape, though appearing like masses of formless protoplasm; also peculiar branched fibres with knob-like swellings at the termination of the branchlets, and lastly a small mass made up of a spirally-twisted fibre, similar to that (represented in Fig. 13) which was found more abundantly in subsequent experiments* where tartrate of ammonia and phosphate of soda were employed.

Experiment 10.—A flask containing a solution† of acetate of ammonia and phosphate of soda, *in vacuo*, which had been hermetically sealed forty-two days previously, after the fluid had been boiled for 20 minutes, was opened on March 10, 1870.

The solution during this time had shown no signs of deposit, turbidity, or pellicle, and on microscopical examination of the fluid, no organisms of any kind were discovered.

Experiment 11.—A flask containing a solution‡ of oxalate of ammonia and phosphate of soda, *in vacuo*, which had been hermetically sealed sixty-one days previously, after the fluid had been boiled for 20 minutes, was opened on March 27, 1870. Its reaction was then found to be slightly acid.

The solution itself continued clear throughout, and presented no scum on its surface; but, after a time, a very small amount of deposit made its appearance at the bottom of the flask, and latterly this had appeared as a small, irregular, and opaque whitish aggregation, with branch-like ramifications. It was very friable and easily broke up into a white granular material. Almost immediately after the neck of the flask had been broken, small acicular crystals appeared in abundance on and in the solution, varying from about $\frac{1}{2}$ to 1 line in length.§

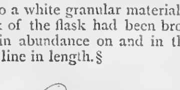

FIG. 10.—Fungus-spores found in Solution of Oxalate of Ammonia.

On microscopical examination, monads and altogether irregularly-shaped particles, showing tolerably active movements, were abundant. A few hyaline spherical vesicles were seen having no solid contents, and some of them were flattened at one pole. Three distinct fungus-spores were seen, and also another otherwise similar body in which there were small granules rather than a single nucleus. There was also a nucleated organism slightly larger, one of whose extremities was rectangular, whilst the other was rounded. In addition, there was a considerable quantity of white granular material which had resulted from the crumbling of large, though opaque white, masses of the same substance; and also some semi-crystalline, opaque rhomboid plates.

Experiment 12.—A flask containing a solution* of tartrate of ammonia and phosphate of soda, *in vacuo*, which had been hermetically sealed eleven days previously, after the fluid had been boiled for 20 minutes, was opened on January 21, 1870. The reaction was then found to be still slightly acid.

No turbidity of the fluid was observed, and no scum formed on its surface, though a very slight deposit gradually collected at the sides and bottom of the vessel, and amongst this there was seen, during the last six or seven days, a small white, flocculent mass, which gradually increased in size.

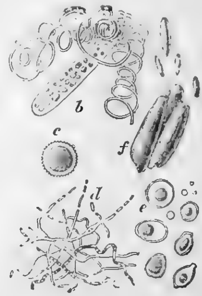

FIG. 11.—Spiral and Confervoid-looking Filaments, with Fungus-spores and Crystals, from a Tartrate of Ammonia Solution.

On microscopical examination of the white mass, this was found to be made up for the most part of a densely interlaced and spirally-twisted fibre, almost precisely similar to what was alluded to in Experiment 9 and to what is represented in Fig. 13, This was colourless, highly refractive, quite homogeneous, and apparently solid. In one place there was seen emerging from amongst the spiral fibres an elongated chamber (*b*) resembling a spore case, and containing many separate protoplasmic-looking masses. At one border of this spirally-twisted fibre-organism, there were a number of other filaments (*d*) about $\frac{1}{20000}''$ in diameter, and containing irregular masses of protoplasm in their interior. These were colourless confervoid-looking filaments.

A few moving monad-like particles were seen, and in the sediment there were many motionless aggregations of such particles imbedded in an almost invisible and scanty jelly-like matrix. In these masses rounded or ovoid fungus-spores (mostly with large nuclei in their interior, in various stages of formation) existed pretty abundantly (*e*). Some of the spores showed a slight neck-like projection and flattening at one extremity, as though they were about to germinate. In addition another much larger spore (*c*) was found. Some of the rounded crystals which were met with in this solution are also represented (*f*).

Experiment 13.—A flask containing a solution† of tartrate of ammonia and phosphate of soda *in vacuo*, which had been hermetically sealed twenty days previously, after the fluid had been boiled for 20 minutes, was opened on February 15, 1870. The reaction of the fluid was then decidedly acid.

The fluid itself showed no signs of turbidity, and there was no trace of scum on its surface. Small whitish flocculent shreds had, however, been seen at the bottom of the flask for the last twelve or fourteen days, during which time they seemed very slowly to increase in size. Some smaller sedimentary particles were also seen at the bottom.

On microscopical examination some of the white shreds were found to be composed of comparatively large masses of the small algoid filaments which were met with in the last experiment; whilst others were made up of an aggregation of fungoid spores with an abundant mycelium which had been developed from them. The spores were precisely similar to those which

* This fibre growth was twisted around a paper-fibre, but there is little doubt that it had simply grown round this as a mere foreign body. Every part of the paper fibre showed the most distinct colour reactions with the polariscope, though the spirally-twisted fibre did not show a trace of such reaction.

† Reaction neutral. ‡ Reaction neutral.

§ Two days before this flask was opened, it was removed for a few hours into another room, where the temperature was lower. The agitation of the fluid, and perhaps in part the lower temperature, soon resulted in the formation throughout the fluid of a number of large acicular crystals from $\frac{1}{2}$ to 1 inch in length. These disappeared in the evening as soon as the temperature of the solution was again raised to about 80° F. The greatly superior size of the crystals produced *in vacuo* is worthy of note.

* Reaction slightly acid. † Reaction slightly acid.

were found in the last solution. There they were about to germinate, and here they had germinated into a fungus of the *Penicillium* type. In one mass the mycelium had produced four or five much larger filaments, terminating in artichoke-like heads of different sizes, bearing naked spores. Though two of the organisms met with in the last experiment were here reproduced, this was not the case with the spirally-twisted fibre organism.

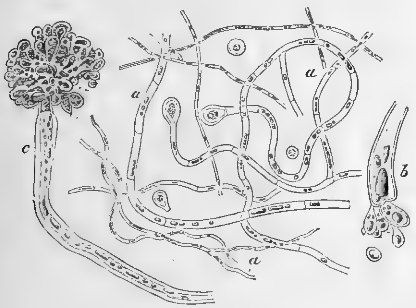

FIG. 12.—Fungus found in the Solution containing Tartrate of Ammonia and Phosphate of Soda.

A few actively moving granules and particles of various shapes were seen, though, as in the last solution, there was nothing resembling a bacterium. Spherules which seemed to represent different stages in the development of the fungus-spores were met with, varying in size from that of an almost inappreciable speck up to that of the perfect spore, which itself varied considerably in size at the time that it began to germinate. In one of these fungus-spores which was about half grown, the nuclear particle within was seen actively moving from end to end of the cell.*

Experiment 14.—A saturated solution of tartrate of ammonia and phosphate of soda *in vacuo*, prepared in same manner as the last solution and at the same time, though opened on the thirty-fifth day, yielded no organisms of any kind.

Experiment 14*a*.—(In this and in the following experiment the solutions were not contained *in vacuo*, but were intended rather to throw light upon the question as to whether the vacuum was favourable or prejudicial to the appearance and growth of organisms in these saline solutions.)

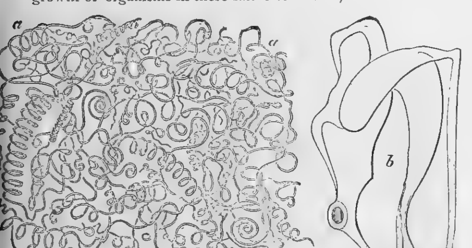

FIG. 13.—Spirally Twisted Fibre Organism.

A solution of tartrate of ammonia and phosphate of soda in distilled water was boiled for 20 minutes, and was then allowed to cool, so as to become filled with air at ordinary atmospheric pressure (which might have contained living germs, since no precaution was taken to destroy them). The neck of the flask was then hermetically sealed, and this was not opened till the thirty-eighth day, when the fluid was found to have a decidedly acid reaction.

The fluid never showed any signs of turbidity, and no pellicle formed on its surface, though a small white flocculent mass had been seen at the bottom of the flask for three weeks, which very slowly increased in size.

The white mass (Fig. 13, *a*) was picked out, and on microscopical examination it was found to be made up for the most part of a spirally-twisted fibre organism, very similar to that which was produced in a similar solution *in vacuo*. The spiral twisting was, however, even more marked, and the fibre in many places was somewhat thicker.*

In addition, two or three small fungus-spores were seen, very similar to those met with in Experiment 12; and there were also some confervoid-looking filaments with irregular masses of protoplasm in the interior, occurring sparingly here and there, similar to those which were met with in much larger quantity in the former experiment. Four or five larger cells were seen with very thick walls, closely resembling the sporangia of some fungi, and in one of them, measuring $\frac{1}{1000}''$ in diameter, many granules were present exhibiting the most active molecular movements. The contents of the other cells could not be made out, as they were so much obscured by the fibre organism in the midst of which they were imbedded.

Experiment 14*b*.—A solution of tartrate of ammonia and phosphate of soda in distilled water, without having been boiled, was exposed to the air † in a flask, and was then examined microscopically on the thirtieth day. The re-action of the fluid at this time was neutral.

There was no pellicle on, or opacity of the fluid, but a small whitish mass of matter had been seen at the bottom of the flask for the last fortnight, which slowly increased in size, till at last it formed a mass bigger than a mustard seed.

On microscopical examination this whitish flocculent matter was found to be made up principally of an enormous aggregation of *Sarcina*-like material, the divisions of which were rather more sharply defined though they were about equal in size to the *Sarcina* which is occasionally met with in urine.

Several fungus-spores were also seen (Fig. 13, *c*) larger than, though otherwise similar to, those met with in *Experiments* 12, 13, and 14*a*. There were none of the confervoid-looking filaments or of the spirally-twisted organisms.

* In Experiments 12 and 13, the actual strength of the saline solutions was not known, but in these as well as in Experiments 14*a* and 14*b*, there may have been about 15 grains of tartrate of ammonia, with about 5 grains of phosphate of soda to an ounce of water.

* It has been suggested to me by a friend whose opinion carries great weight with it, that this is not an organism which had grown in the solutions, but rather some non-living accidental product which had gained access to the solutions. This was a suggestion which deserved a most attentive consideration, more especially as in two other experiments, which will not be cited, foreign bodies were found in the solutions. Are these spiral-fibre masses, then, mere non-living *débris* of some kind? It was suggested that they were spiral ducts of some plant broken up and modified by the boiling process which they had undergone.

With reference to this question it seems most desirable to state, in the first place, that such a spiral-fibre mass has been met with four times in solutions containing a mixture of tartrate of ammonia and phosphate of soda, though never in solutions containing tartrate of ammonia alone, and in fact it has never been found in any other kind of solution except in one whose chemical constitution was almost precisely similar to the mixture above named. This seemed to indicate that it might have been contained within or upon the crystals of phosphate of soda. Successive solutions, however, of many of these in a watch-glass have shown no trace of such fibre-masses (and it may be well to add, perhaps, that a similar statement holds good for the crystals of tartrate of ammonia). These masses of spiral fibre, found only in solutions of a given chemical constitution, have been seen to increase in size from week to week. The Rev. M. J. Berkeley, who was kind enough to examine my specimens, could not identify them with any known cryptogamic organisms.

If they were really altered spiral ducts, then, seeing that they have only been met with in solutions of a certain chemical constitution, they ought to have been contained in the saline substances employed. But an examination of such saline substances as above stated, does not show a trace of these fibre-masses. All the spiral ducts which I have examined, moreover—even after boiling—polarise beautifully, whilst these spirally twisted fibre-masses do not give the least trace of colour reactions with polarised light. And lastly, in certain parts the apparently solid spiral fibre seems to become decidedly tubular, and in other places it widens out into flat expansions of a peculiar character. In one of these expansions (Fig. 13, *b*) differentiation had apparently taken place, which had led to the production of a spore-like body.

A somewhat similar twisted fibre-organism was met with in Experiment 16, though here it was evidently in an embryonic condition. (Fig. 15.) It seemed to be then arising by a process of differentiation taking place in a pellicular mass.

† A piece of paper merely, was loosely inserted into the mouth of the flask with the view of keeping out as much dirt as possible.

Experiment 15.—A flask containing a solution of a potash-and-ammonia alum, and of tartar emetic, *in vacuo*, which had been hermetically sealed twenty-eight days previously, after the fluid had been boiled for fifteen minutes, was opened on March 17, 1870. The fluid then had a decidedly acid reaction.*

The solution continued clear throughout; there was no trace of a pellicle and no deposit at the sides, though a whitish flocculent mass was seen at the bottom of the flask after the first fortnight, which gradually increased in amount, and at last formed a mass about $\frac{1}{8}''$ in diameter.

On microscopical examination the white mass was found to be made up of aggregations of variously sized and irregularly shaped protein-looking particles which were imbedded (*b*) in a most distinct hyaline jelly-like material. The granules were highly refractive, altogether irregular in shape, and they varied in size from $\frac{1}{3000}''$ up to $\frac{1}{5000}''$ in diameter. Though most of the particles

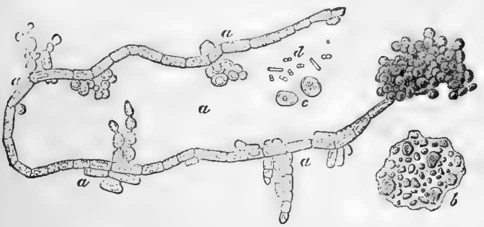

FIG. 14.—Fungus met with in a solution containing Potash-and-Ammonia Alum, with Tartar Emetic.

were motionless and imbedded in the jelly, very many were seen exhibiting active and independent movements; some of these were in the form of little double spherules (*d*), and a very few others resembled bacteria about $\frac{1}{8000}''$ in diameter, though they did not possess the accustomed joint.

Three fungus-spores with thick double walls were seen. Each these was about $\frac{1}{3300}''$ in diameter. Within one of them there were only a number of granular particles (*c*), but within each of the other two there was a large and somewhat irregular nuclear mass.

In addition there was found the complete fungus which is represented in the figure (*a*), with all its spores. In a portion of one of the granular aggregations, a mass of about thirty spores seemed to be undergoing evolution in a part of the mucoid material through which some fine granules were disseminated.

Experiment 16.—A flask containing a solution of carbonate of ammonia and phospate of soda *in vacuo*, which had been hermetically sealed thirty days previously after the fluid had been boiled for twenty minutes, was opened on March 1, 1870. The fluid was then found to have a very slightly alkaline reaction.

The fluid had continued clear and no pellicle had formed on its surface, though a light granular deposit had slowly collected in small quantities on the bottom and sides of the flask.

On microscopical examination, bright highly refractive moving particles, very similar in appearance to those of milk, were met with, of all sizes varying between $\frac{1}{30000}''$ and $\frac{1}{5000}''$ in diameter. There were also numerous crust-like aggregations of such particles. Small *Torula* cells, the smallest being about $\frac{1}{15000}''$ in diameter, were very abundant. They were either single or double, and each cell contained a distinct nuclear particle; some of the larger ones, indeed, contained two. All these cells exhibited very slight oscillating movements. Two cellular looking bodies, each about $\frac{1}{2000}''$ in diameter, and having granular contents, were also seen; and, in addition, there were two or three patches of a peculiar spirally twisted fibre-like organism, growing in portions of the granular crust, and apparently representing an embryonic condition of a spiral fibre, closely resem-

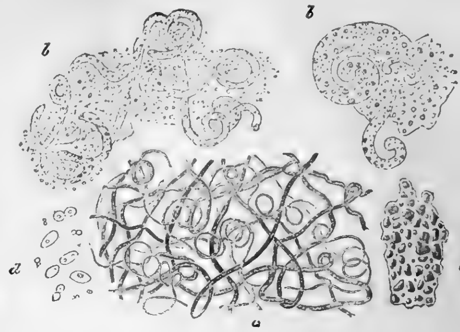

FIG. 15.—Embryonic condition, and also more mature stage, of a Spiral-fibre Organism met with in a solution of Carbonate of Ammonia and Phosphate of Soda.

bling those met within previous experiments. Neither of these gave the smallest trace of a colour reaction with the polariscope.

B.—*Experiments in which the fluids employed were raised to a temperature of from 146° to 153° C. for four hours, after all air had been exhausted and the flasks had been hermetically sealed.*

A temperature of 100° C. has been the degree of heat to which all the fluids in the experiments hitherto related have been subjected. It has been previously found that none of the lower organisms so treated, and which had been afterwards examined, were able to survive an exposure for a few seconds to such a degree of heat. They had nearly all been destroyed, in fact, at a temperature many degrees short of this. Many different kinds of organisms have been submitted to this test, and without the occurrence of any exceptions* such a degree of heat has always proved fatal to them. Looking, therefore, on the one hand, at the uniformity in the experimental evidence, which has itself extended over a wide basis, and, on the other, at the comparative uniformity in fundamental nature and property existing between all the lowest kinds of Living things, which are almost wholly made up of a more or less naked living matter or protoplasm, it is only reasonable for us to conclude, until direct evidence can be adduced to the contrary, that that which holds good for the many without exception may prove to be a rule of universal application. Therefore it was that the Societé de Biologie (and M. Pasteur himself for a long time) assumed that none of the lower kind of organism could survive in a fluid which was raised to a temperature of 100° C.

No evidence has as yet been adduced which is capable of shaking the validity of this conclusion, and the experiments just related are much stronger in favour of the view that the organisms found in my experimental fluids were there evolved *de novo* than were all the negative results in the experiments of Schwann (upon which so much stress was formerly laid) in proving the impossibibility of such a mode of evolution. And yet Schwann's experiments were deemed by many so conclusive that they were thought to have upset the doctrine of heterogeny. The fluids with which he experimented were only exposed to a temperature of 100° C., and, working under a particular set of conditions which are considered to be adverse to the occurrence of evolutional changes, he found no organisms therein when his flasks were opened. I, on the contrary, subjecting my experimental fluids to the same temperature, though exposing them subsequently to quite different conditions, which I suppose to be more favourable for the occurrence of evolutional changes, do find organisms in the fluids when the flasks are opened. His negative results *may* be only applicable to the particular fluids and the particular conditions under which he worked; but my

* This solution was prepared one evening when I had been busy in devising several other mixtures with which I deemed it desirable to experiment. At the time I thought I possessed a pure potash alum, and by some strange oversight I had failed to recognise that, if this had been the case, I should have been employing a solution which contained no nitrogen. Having once planned what mixtures I would use, I did not further think of each of them analytically. It was not, therefore, till my attention was called by Dr. Sharpey to the assumed absence of nitrogen in the above solution, that I became aware of this. It seemed very incredible that an organism should have been produced in a solution containing no nitrogen. I then had some of my supposed potash alum carefully tested, and it was found to contain a considerable quantity of ammonia. I then also learned that as ammonia-alum is now the alum of commerce, it is very difficult to get a pure potash alum.

* No exceptions, that is, amongst such organisms as are met with in infusions. The only known exceptions to that rule being met with in the case of seeds naturally provided with a hard *testa*, and after these had undergone an extreme amount of desiccation.

positive results, and those of many other experimenters, may be considered to have a most important bearing upon the settlement of the general doctrine. It becomes simply a question as to whether the conditions which were formerly believed sufficiently stringent to destroy all pre-existing Living things within the experimental flasks are in reality adequate to effect this. Can the standard of vital resistance be raised? If the old landmarks cannot be shown to be false, then there is very far more evidence of all kinds in favour of, than there is against, the occurrence of "spontaneous generation."

But in order, still further, to put this question beyond the region of doubt, I gladly availed myself of Prof. Frankland's proffered aid. He very kindly offered to procure a perfect vacuum in my flasks, and then, after these had been hermetically sealed, to expose them and the fluids which they contained for some time to a temperature of about 150° C. This temperature for a fluid is so very far in advance of that which is at present believed to be destructive to all the lower organisms, that it is perfectly fair for us to presume, till evidence be adduced to the contrary, that Living things would be completely destroyed by an exposure to such a temperature even for a single minute.

It seemed desirable to try different kinds of solutions in this way, and I therefore asked Dr. Frankland to be kind enough to submit four flasks and their contents to this most stringent test. In order that they might be representative of the solutions with which I had already been working, one was to contain a freshly prepared and filtered infusion of turnip; another a solution of sugar, tartrate of ammonia, and phosphate of soda in distilled water; another a solution of tartrate of ammonia and phosphate of soda alone in distilled water; whilst the last was to contain carbonate of ammonia and phosphate of soda in distilled water.

The second of these solutions was submitted to these conditions by Dr. Frankland, on Feb. 11, 1870, together with two others, one containing turnip juice, and the other carbonate of ammonia and phosphate of soda. On the following day I received a letter from Dr. Frankland, in which he had written as follows:—"Yesterday, I exposed the three liquids to a temperature of 150° C. for four hours. On taking them out of the digester this morning two were broken; one had probably burst with the pressure of carbonate of ammonia vapour, the other had received some slight shock which had broken off the extreme point of glass where it was drawn off before the blowpipe. The third, containing the tartrate of ammonia, sugar, and phosphate of soda, I send along with this, but fear you will not consider its contents favourable for your operations, part of the sugar having apparently been converted into caramel."

A few days afterwards (on Feb. 15) Dr. Frankland submitted the three other solutions to a similar treatment, and he has kindly furnished me with the following statement of the conditions to which they were subjected:—

"Each liquid was placed in a glass tube about $\frac{3}{4}$ inch in diameter, 9 inches long, and closed at one end by fusion of the glass. The open end of the tube was then drawn out so as to form a thick capillary tube, which was afterwards connected with a Sprengel's mercurial pump. The action of the pump soon produced a tolerably good vacuum, when on gently warming the liquid, the latter began to boil, its vapour expelling the last traces of air from the apparatus. After the boiling had been continued for several minutes, the tube was hermetically sealed at the capillary part.

"Three tubes were prepared in this way, containing respectively—

"1. Turnip juice;

"2. Solution of ammonic tartrate and sodic phosphate;

"3. Solution of ammonic carbonate and sodic phosphate.

"The vacuum in tubes Nos. 1 and 2 was so perfect as to render them good water-hammers. In the third tube the vacuum was not so good, owing, doubtless, to the evolution of carbonic anhydride from the ammonic carbonate.

"The three tubes were now placed in the wrought iron digester, described by me in the Philosophical Transactions for 1854, page 260. It consists essentially of a cylindrical iron vessel, with a tightly fitting cover, which can be securely screwed on to it. Through the centre of the cover passes an iron tube, which descends half way down the centre of the cylinder. This tube is closed at bottom, and contains a column of mercury about an inch long, and a thermometer plunged into the mercury shows the temperature of the liquid inside the digester.

"Water being now poured into the digester until it covered the tubes, and the cover having been screwed on, heat was applied by means of a gas stove.

"The temperature was allowed to rise to about 150° C., and was maintained between 146° and 153° C. for four hours, and it is almost needless to say that every part of the sealed tubes and their contents was exposed to this temperature during the whole time. The glass tubes, though of moderately thick glass only, ran no risk of fracture, because the pressure inside them was approximately counter-balanced by the pressure of steam outside.

"After cooling, the tubes were removed from the digester, when it was found that the turnip juice had become discoloured, and the liquid no longer acted as a water-hammer, showing that the vacuum in the tube had been impaired. The contents of the two remaining tubes were apparently unaltered, the vacuum in No 2. being as perfect as ever."

Experiment 17.—The tube containing the infusion of turnip was opened at the end of the twelfth day.

When received from Dr. Frankland the fluid had been changed to a decided, but light brown colour, and there was some quantity of a blackish brown granular sediment at the bottom, though the solution was free from all deposit when placed in the digester. After this tube was suspended in the warm place, as the others had been, it remained in the same position till it was taken down to be opened. A slight scum or pellicle was observed on the surface—covering this partially—on the sixth day. During the succeeding days it did not increase much in extent, though it became somewhat thicker. Although very great care was taken, still the slight movement of the flask, occasioned in knocking off its top, caused this pellicle to break up and sink to the bottom.*

The contents of the flask emitted a somewhat fragrant odour of baked turnip, and the reaction of the fluid was still slightly acid. On microscopical examination, there was found very much mere granular *débris* of a brownish colour, which probably represented the brownish sediment seen when the tube was removed from the digester. There were, also, a very large number of dark apparently homogeneous reddish brown spherules, mostly varying in size from $\frac{1}{7500}''$ to $\frac{1}{20000}''$ in diameter, partly single and partly variously grouped; the nature of these was doubtful though they were probably concretions of some kind. There were also other indeterminate flat and irregular masses, which seemed more to resemble protoplasmic substance in its microscopical characters.

In addition, many irregular and monad-like particles were seen in active movement, though there were no distinct bacteria.

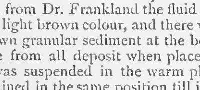

FIG. 16.—*Tailed Monad* and *Torula* Cell from a Turnip Solution which had been exposed to a temperature of 146°—153° C. for four hours.

Several rod-shaped bodies $\frac{1}{2000}''$ in length (*d*) were seen, however, resembling ordinary bacteria, except that they were unjointed and motionless.† In one of the drops examined there was a delicate tailed monad in active movement—a specimen of *Monas lens*, in fact, $\frac{1}{7500}''$ in diameter, having a distinct vacuole in the midst of the granular contents of the cell. Another ovoid body was seen, about the same size, without a tail and motionless, though it contained two nuclear particles within.‡

* It was owing to the appearance of the pellicle and the seeming likelihood of its breaking up and sinking to the bottom if allowed to remain, as I had known others do, that I was induced to open this tube so early. I thought it possible that nothing else might form afterwards. I felt anxious to be able to examine this pellicle before it got mixed with the granular matter at the bottom.

† The bacteria which appear in a simple solution of tartrate of ammonia, however, frequently remain motionless for a very long time, and the *bacteridia* of Davaine are both unjointed and motionless.

‡ Although these were the only bodies of this kind actually seen, it is worth noting that only five or six drops of about the whole ounce and a half of fluid were submitted to examination. This solution was undoubtedly examined rather prematurely. In another turnip solution which has been subsequently exposed in Dr. Frankland's digester to a temperatnre of 146° C. for a shorter time, and which was opened on the 67th day (the details of which I shall

Experiment 18.—The tube containing white sugar, tartrate of ammonia, and phosphate of soda in distilled water, was opened on the fortieth day after it had been heated in the digester.

When received from Dr. Frankland, this solution, instead of being colourless, was of a dark brownish-black colour, not unlike that of porter, this change of colour being apparently due to the conversion of some of the sugar into caramel; though it was free from any notable deposit. After about the fortieth day a thick iridescent scum gradually formed over the whole surface‡, and continued visible for more than a week. It afterwards disappeared, and then I noticed for the first time a large quantity of a brownish-black sediment at the bottom of the flask. No scum again formed on the surface, and no other change was seen to take place in the fluid.

When opened there was no very appreciable odour, though the reaction of the fluid was strongly acid.

On microscopical examination, the deposit was found to be made up in great part of dark, reddish-brown, or ruby-red coloured globules of various sizes, partly single, and partly in various kinds of aggregation. They varied in size from a minute speck $\frac{1}{20000}$" in diameter up to large spherule $\frac{1}{1428}$" in diameter. They presented no trace of structure, and were apparently quite homogeneous. Although larger, they resembled in other respects those which had been met with in the turnip solution. Other bodies, however, were seen, which presented much more obvious evidence of being concretions. They were mostly light brown in colour, some of the smaller somewhat resembling cells, with granular contents, whilst some of the larger, about $\frac{1}{2000}$" in diameter, showed concentric markings, with or without the presence of a darker central nucleus of varying size. Some again were composite structures—each spheroidal as a whole, though made up of a close radiating aggregation of ovoidal bodies around such a central nucleus. None of these spherules showed any colour reactions with the polariscope. I regarded them all as non-living concretions of a doubtful nature

Two fresh looking fungus-spores were seen, however, of the most unmistakeable character. One, apparently just about to sprout, was $\frac{1}{7600}$" in diameter; it had thick walls and a large central nucleus $\frac{1}{12000}$" in diameter. The other was a smaller and more delicate-looking body, having more the appearance of a *Torula* cell. There were also some figure-of-eight-shaped bodies about $\frac{1}{20000}$" in diameter, which were moving about most actively.

In addition, there were a multitude of particles altogether irregular in shape, in most active movement, having a protoplasmic appearance. Some were altogether irregular particles others were larger and more elaborate masses; whilst others—still exhibiting slow movements—were lozenge-shaped, or more or less cuboidal.

Experiment 19.—The tube containing tartrate of ammonia and phosphate of soda in distilled water was opened on the sixty-fifth day.

When received from Dr. Frankland, the solution in this tube was quite colourless, clear, and free from visible deposit. About the fifth or sixth day, however, after it had been suspended in a warm place, a number of small, pale, bluish-white flocculi made their appearance throughout the solution, and continued always in the same situation except when the fluid was shaken,—owing apparently to their specific weight being the same as that of the fluid itself. The contents of the flask were repeatedly scanned with the greatest care with the aid of a lens, though nothing else could be seen until about the expiration of a month. Then there was observed, attached to one of the flocculi about ¼" from the bottom of the vessel, a small, opaque, whitish speck, little bigger than a pin's point. This increased very slowly in size for the next three or four weeks, and then another smaller mass also made its appearance. At the expiration of this time the larger mass was more than ⅛" in diameter, and both could be and were seen by several people with the naked eye. In the last three weeks previous to the opening of the flask it was often remarked that the mass did not appear to have at all increased in size.

Before the flask was opened it was found that it only acted as a water-hammer to a trifling extent, though when the narrow end of the flask was broken off there was a slight dull report, and a quantity of small particles of glass were swept by the in-rush of air into the fluid. There had still, then, been a partial vacuum in the flask. The reaction of the fluid was found to be slightly acid.

This flask was opened in Dr. Sharpey's presence. He had examined the white masses previously with a pocket-len , and when the flask was broken the larger white mass issued with some of the first portions of the fluid, which were poured into a large watch-glass. This was at once taken up on the point of a penknife and transferred to a clean glass slip, when it was immersed in a drop of the experimental fluid and then protected by a thin glass cover. On microscopical examination we at once saw that the whitish mass was composed of a number of rounded and ovoidal spores, with mycelial filaments issuing from them in all

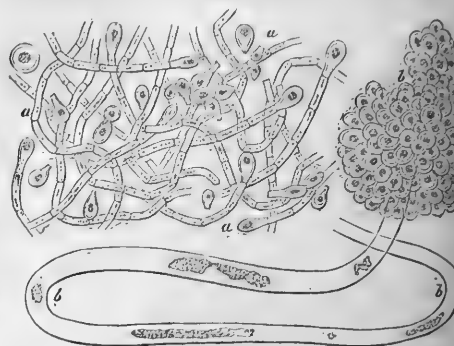

Fig. 17.—Fungus obtained from a solution of Tartrate of Ammonia and Phosphate of Soda which had been exposed to a temperature varying between 146° and 153° C. for four hours.

stages of development. The spores varied much in shape and dimensions; the prevalent size being about $\frac{1}{3500}$" in diameter, though one was seen as much as $\frac{1}{2000}$" in diameter. They all possessed a single rather large nucleus, which was mostly made up of an aggregation of granular particles. Some were just beginning to develope mycelial filaments, and others had already given origin to such filaments about $\frac{1}{4800}$" in diameter, in which there were scattered some colourless protoplasmic granules, but no vacuoles. Contiguous to these fresh and evidently Living portions of the plant, there were other parts in all stages of decay, in which the remains of the filaments were seen in the form of more or less irregular rows of brownish granules representing the altered protoplasmic contents of a previous filament whose walls were now often scarcely visible. Subsequently the smaller white mass was picked out, and this was found to contain some living mycelium and spores, and also a considerable patch of decaying filaments, in connection with which ther was a long and broader filament bearing at its distal extremity a large aggregation of more than 100 spores, quite naked, and very similar in character to those from which the mycelial threads arose. This plant was evidently a *Penicillium* quite similar to what had been obtained from a tartrate of ammonia and phosphate of soda solution on a previous occasion after twenty-one days (*Experiment* 13), and its spores were also similiar to those which had appeared in another solution (*Experiment* 11) of the same kind after eleven days.

The delicate flocculi which first made their appearance in the solution, and which persisted throughout, seemed to be made up of aggregations of the finest granules, which, however, became almost invisible when the flocculi were mounted in glycerine and carbolic acid.

Experiment 20.—The tube containing carbonate of ammonia and phosphate of soda in distilled water, was opened on the thirtieth day in the presence of Prof. Huxley.

When this flask was received from Dr. Frankland, the fluid was somewhat whitish and clouded. During the last ten days a thin pellicle had been seen gradually accumulating on its surface, and in the latter four or five days this increased much in thickness, and gradually assumed a distinct mucoid appearance. The fluid itself was tolerably clear, though an apparent turbidity was given by the presence of a fine whitish deposit on the sides of the glass.

afterwards publish), *Torula* cells, and fungus-spores with developing filaments, were formed in very large numbers, in company with other living organisms.

‡ This was much larger than that exposed in the other three vessels, owing to the fluid being contained in a small flask instead of in a tube.

When the flask was opened, the reaction of the fluid was found to be neutral.

Portions of the pellicle were at once transferred to a glass microscope slip, and then, protected by a covering glass, were submitted to a prolonged microscopical examination.* A number of little figure-of-eight particles, each half of which was $\frac{1}{20000}$" in diameter, were seen in active movement, even in situations where they could not have been influenced by currents. The portions of the pellicle were made up of large, irregular, and highly refractive protein-looking particles imbedded in a transparent jelly-like material. The particles were most varied in size and shape, being often variously branched and knobbed. There were also seen several very delicate, perfectly hyaline, vesicles about $\frac{1}{2000}$" in diameter, these being altogether free from solid contents.

A subsequent and most careful examination of a considerable quantity of the granular matter of the pellicle which had been mounted on two microscope-slips,† and at once protected by surrounding the covering glasses with cement, revealed five spherical or ovoid spores the average size of which was about $\frac{1}{3300}$" in diameter. They all possessed a more or less perfectly-formed

FIG. 18.—Fungus-spores found in a Carbonate of Ammonia and Phosphate of Soda Solution which had been exposed to a temperature varying from 146° to 153° C. for four hours.

nucleus, and all showed a most distinct doubly-contoured wall. One of the smaller of them showed that it had reached a stage where it was about to germinate. In addition, one small mass of *Sarcina* was seen, not very distinctly defined, owing to its being still in a somewhat embryonic stage.

H. CHARLTON BASTIAN

(*To be concluded.*)

NEW OBSERVATORY AT THE MAURITIUS

(*Communicated.*)

HIS Royal Highness the Duke of Edinburgh and his Excellency Sir Henry Barkly, attended by their respective suites, arrived at the site of the New Observatory at half past ten on Monday morning, May 30th, and were received by the President and Council of the Meteorological Society.

The architect of the building, Mr. Bowdler, of the Surveyor General's Department, and Mr. Horne, of the Royal Botanical Gardens, had elegantly decorated the grounds and the enclosed space around the massive stone.

The President, Captain Russell, R.N., read and presented the following address :—

"*To Captain His Royal Highness* ALFRED ERNEST ALBERT, *Duke of Edinburgh, Earl of Ulster, Earl of Kent, K.G., K.T., G.C.M.G., G.C.S.I., R.N., &c.*

"May it please your Royal Highness,

"We, the President and Council of the Meteorological Society of Mauritius, beg leave to approach your Royal Highness with the assurance of our loyalty to the Crown, and of our devoted attachment to Her Majesty the Queen and the Royal Family.

"We desire to offer to your Royal Highness a cordial welcome to these shores.

"Mauritius being admirably situated for meteorological and magnetical observation, it has long been the ardent wish of the Society that an Observatory, fully equipped wtth instruments of the most approved construction, should be permanently established for that purpose.

"Through the wise and liberal policy of the late Sir William Stevenson, and more immediately that of our present Governor and Patron, his Excellency Sir Henry Barkly, the moment for commencing the principal building has now arrived.

"We therefore hail with joy the auspicious occasion which allows us to request that your Royal Highness will be pleased to lay the Foundation Stone.

"Meteorological and magnetical researches, having for one of their main objects the safety and welfare of Navigation, touch closely the commercial prosperity of the world, and link together men of every nation by the cords of a common interest. Your Royal Highness, therefore, being not only an Officer in the Naval Service of a Queen whose ships traverse every sea, and whose Dominions extend to the remotest shores, but also the Son of an Illustrious Prince, who was ever foremost in encouraging Science, there could not, we venture to to think, be a more fitting Monument of the visit of your Royal Highness to Mauritius than a building to be specially devoted to objects with which your Royal Highness's experience cannot fail to prompt a generous sympathy.

"With our warmest wishes for your Royal Highness's welfare and happiness, and with renewed assurances of our devotion to our beloved Sovereign's Person and Family,—We have the honour to be, with the highest respect, your Royal Highness's most humble and most dutiful Servants,

"(Signed) James Tho. Russell, R.N., *President;* H. J. Jourdain, *Vice-President;* A. J. W. Arnott. *Treasurer;* J. C. Browne, C. Bruce, A. B. Commins, M. Connal, J. H. Finniss, Robt. Leech, George McIrvine, *Council;* C. Meldrum, *Secretary.*"

His Royal Highness replied in the following terms :—

"*To the President and Council of the Meteorological Society.*

"Gentlemen,

"I beg to thank you most heartily for your cordial welcome. It will afford me sincere pleasure to lay before Her Majesty the assurance of loyalty and devotion conveyed in your address.

"As an officer in the navy, I fully appreciate the advantageous position of this island for meteorological and magnetical observation, and it is with great satisfaction that I proceed to comply with your invitation of laying the foundation stone of a building to be specially devoted to objects of such importance.

"Your expressions of affectionate interest in all that concerns my future welfare and usefulness in the career which, by God's will, may be before me, are such as to demand a no less cordial response on my part.

"May this ceremony be auspicious to all concerned, and I sincerely trust that the Observatory, when completed, may realise all the expectations of its promoters, and continue throughout the future, not only a source of utility to the colony itself, but an aid to the cause of science, and a blessing to navigators throughout the world.

"(Signed) ALFRED."

The ceremony of laying the foundation stone was then proceeded with. His Royal Highness first deposited in a recess in the lower stone a bottle containing coins of the realm, a copy of the address, newspapers of the colony, and a paper on which was engrossed the following inscription :—

"This foundation stone of the Mauritius New Observatory was laid by Captain H.R.H. the Duke of Edinburgh, in presence of H. E. Sir Henry Barkly, K.C.B., F.R.S., Governor and Commander-in-Chief of Mauritius, at the request of the Meteorological Society, on Monday, the 30th of May, 1870."

His Royal Highness then spread the lower stone with mortar, and the upper stone was lowered into its bed. The Prince afterwards tried the stone with plumb-rule, level, and gavel in right masonic style, and declared it well and truly laid.

The trowel used by his Royal Highness, and presented to him by the society, was of solid silver, elegantly chased and of beautiful form. It was manufactured by Mr. G. Lewison, of Royal Street, and had engraved on it the following inscription :—

"Presented to His Royal Highness Alfred Ernest Albert, Duke of Edinburgh, K.G., K.T., G.C.S.I., R.N., by the Meteorological Society of Mauritius, at the laying of the Foundation Stone of a new Meteorological and Magnetical Observatory. Mauritius, 30th May, 1870."

The Secretary, Mr. Meldrum, then addressed his Royal Highness as follows :—

* Professor Huxley examined portions of the pellicle as soon as they were removed. He at once admitted the general resemblance as regards microscopical characters between this and the pellicle which forms on solutions containing organic matter. The particles were, however, mostly indefinite in shape rather than definite, though they were obviously imbedded in a clear jelly-like material. They became deeply tinted, also, when tested with a weak magenta solution, in the same way that the monads and bacteria of an ordinary pellicle are tinted by such a fluid, whilst the jelly-like material only assumed the faintest tinge of colour.

† These were the two specimens which were mounted in Prof Huxley's presence, and which were examined by him. After he left I spent more than two hours in thoroughly searching over these specimens with a $\frac{1}{12}$" objective. And the result was that five fungus-spores were found in the two specimens as above stated. These are still in my possession.

"May it please your Royal Highness.—On behalf of the Meteorological Society, and as Government Observer, I have the honour to thank your Royal Highness for having been graciously pleased to lay the Foundation Stone of the Mauritius New Observatory.

"I am sure I only give expression to the feelings with which the Society is animated, when I say that it will ever retain a most grateful sense of the generous sympathy and consideration which have induced your Royal Highness to come here, to-day, at personal inconvenience, to perform the interesting and important ceremony which the Society has had the extreme gratification to witness.

"If anything could enhance the pleasure which the Society now feels, it is the presence, on this auspicious occasion, of his Excellency, Sir Henry Barkly, who, during a long and an arduous administration, has not ceased to take a warm interest in the Society's objects, and to whom will be mainly due the merit of establishing in this distant Colony an Observatory which, I hope, will be second to none of the same nature in other portions of Her Majesty's dominions.

"Engaged for the most part in agricultural and commercial pursuits, but yet dependent for the necessaries of life on importations from other countries, and surrounded by a tempestuous ocean, the people of Mauritius, deeply interested in the progress of meteorological science, and many of them actively occupied in promoting it, will, I have no doubt, long preserve a fond recollection of the part which your Royal Highness has been kind enough to take in this day's proceedings.

"But the labours to be carried on here will be not merely of local utility. I trust they will also contribute to the advancement of meteorology and of terrestrial magnetism generally, as well as of certain branches of physical astronomy. In this respect their chief practical aim will be to render service to the noble profession of which your Royal Highness is so distinguished a member; and next to the pleasure of contemplating the works of the great Author of Nature, I know no stronger incentive to perseverance than the circumstance that the building about to be raised on this solitary spot, in the heart of the Indian Ocean, for the special object of conducting researches calculated to be of use to the maritime nations of the world, will in all future time be associated with the cherished name of England's sailor Prince."

His Excellency the Governor briefly addressed the audience. His Excellency said that he had always, as Mr. Meldrum remarked, taken much interest in the Society, and had done all in his power to promote its objects. It gave him great pleasure that the foundation stone of a new observatory had been laid before his departure from the colony. The ceremony could not have been more appropriately or more gracefully performed than by his Royal Highness, who was not only the second son of Her Majesty the Queen, but also a distinguished naval officer. His Excellency concluded amid general applause, by heartily wishing every possible success to what he would propose to call the Royal Alfred Observatory. Thus terminated these interesting proceedings.

SCIENTIFIC SERIALS

Journal of the Chemical Society, June, 1870.—Messrs. T. Bolas and C. E. Groves give a description of the mode of preparation and the properties of tetrabromide of carbon, the discovery of which they had announced in the preceding number of the Journal. Bisulphide of carbon was digested with an excess of bromine in the presence of terbromide of antimony or of bromide of iodine in a sealed tube of 150° for 48 hours. The bromide can also be obtained from bromopicrin and bromoform by treatment with the same reagents. Tetrabromide of carbon crystallises in white lustrous plates, fusible at 91°, nearly insoluble in water, soluble in alcohol, ether, benzol, and bisulphide of carbon, decomposed by aqueous solutions of potassa and soda at 150°. With care it may be sublimed without decomposition. By reduction by nascent hydrogen it produces bromoform and dibromide of methylene. The authors intend to study the action of argentic oxalate, cyanide, &c., on this interesting compound. Prof. A. H. Church continues his researches on new and rare Cornish minerals, giving the analysis of restormelite, which appears to be kaolinite $Al_2 O_3 2SiO_2$, 2Aq, in which some of the hydrogen is replaced by potassium and sodium and a portion of the aluminium by iron. The specific gravity is 2·58, and the hardness about 2. Chalcophillite contains 8 CuO, $Al_2 O_3$, $As_2 O_5$, 24 or 25 Aq., it loses 13·79 per cent. of water *in vacuo*, corresponding to 11 H_2O; the specific gravity is 2·44. This number also contains the commencement of a very long and elaborate paper on the combinations of carbonic anhydride with ammonia and water, by Dr. E. Divers. The author gives a history of the different compounds which he has examined, and describes no less than nine processes for the preparation of normal ammonium carbonate $CO_2 (OH_2)_2 (NH_3)_2$. Its properties and reactions are also fully given. In the second section, only a portion of which appears in this number, the preparations and properties of the half acid ammonium carbonate are detailed.

THE *Revue des Cours Scientifiques* for June 18, is almost entirely occupied with a translation of Prof. Huxley's address before the Geological Society on the course of palæontology during the last eight years. M. Bernard also proceeds with his course of lectures on suffocation by the fumes of charcoal, which is again continued in the following number, where we find also a paper read before the Congress of German Naturalists and Physicians at Innsbrück by Prof. Kékulé, on chemical work, and a review by Prof. Duclaux, of Pasteur's Researches on the Silkworm Disease. In the number for July 2, is a very important article by Prof. Agassiz on the Gulf Stream, being a report of the dredgings from the bottom of the Gulf Stream, made during the third expedition of the U.S. steamer *Bibb*. Prof. Agassiz believes that in the cretaceous period a current set in in the Atlantic from the north-east to the south-west, North and South America being then distinct continents, and that it was only at a subsequent period that communication between the Atlantic and Pacific became interrupted, and that the Gulf Stream set in in the opposite direction. In the same number is a continuation of M. Berthelot's paper on isomeric states of simple substances, treating especially of sulphur.

SOCIETIES AND ACADEMIES

LONDON

London Mathematical Society, June 9.—Prof. Cayley President, in the chair. The Hon. Sir James Cockle was elected a member. Mr. Spottiswoode, V.P., having taken the chair, the president communicated the following "Note on the Cartesian, with two imaginary axial foci." Let A, A′, B, B′, be a pair of points and antipoints; viz., A, A′, the two imaginary points, co-ords $(\pm \beta i, 0)$; B, B′, the two real points, co-ords $(0, \pm \beta)$, and write $\rho, \rho', \sigma, \sigma'$, the distances of a point (x, y) from the four points respectively, say

$$\rho = \sqrt{(x + \beta i)^2 + y^2} \qquad \rho' = \sqrt{(x - \beta i)^2 + y^2}$$

$$\sigma = \sqrt{x^2 + (y + \beta)^2} \qquad \sigma' = \sqrt{x^2 + (y - \beta)^2}$$

we have

$$\rho^2 + \rho'^2 = 2 (x^2 + y^2) - 2 \beta^2$$
$$= \sigma^2 + \sigma'^2 - 4 \beta^2$$

$$\rho\rho' = \sqrt{(x + \beta i + yi)(x + \beta i - yi)(x - \beta i + yi)(x - \beta i - yi)}$$
$$= \sigma \sigma'$$

and thence

$$(\rho + \rho')^2 = (\sigma \times \sigma')^2 - 4 \beta^2$$
$$(\rho - \rho')^2 = (\sigma - \sigma')^2 - 4 \beta^2$$

or say

$$\rho + \rho' = \sqrt{(\sigma + \sigma')^2 - 4 \beta^2}$$
$$i(\rho - \rho') = \sqrt{4 \beta^2 - (\sigma - \sigma')^2}$$

The equation of a Cartesian having the two imaginary axial foci, A, A′, is

$$(p + qi) \rho + (p - qi) \rho' + 2 k^2 = 0$$

viz., this is,

$$p (\rho + \rho') + q i (\rho - \rho') + 2 k^2 = 0$$

or what is the same thing, it is

$$p \sqrt{(\sigma + \sigma')^2 - 4 \beta^2} + q \sqrt{4 \beta^2 - (\sigma - \sigma')^2} + 2 k^2 = 0$$

which is the equation expressed in terms of the distances σ, σ', from the non-axial real foci, B, B′. The radicals are to be taken with the signs ±. This equation gives, however, the Cartesian in combination with an equal curve situate symmetrically therewith in regard to the axis of y.

The distance σ, σ' may conveniently be expressed in terms of a single variable parameter θ; in fact, we may write

$$\pm p \sqrt{(\sigma + \sigma')^2 - 4 \beta^2} = - k^2 - k\theta$$
$$\pm q \sqrt{4 \beta^2 - (\sigma - \sigma')^2} = - k^2 + k\theta$$

that is

$$\sigma + \sigma' = \sqrt{4\beta^2 + \frac{k^2}{p^2}(k + \theta)^2}$$

$$\sigma - \sigma' = \pm\sqrt{4\beta^2 - \frac{k^2}{q^2}(k - \theta)^2}$$

So that assigning to θ any given value, we have σ, σ', and thence the position of the point on the curve. We may draw the hyperbola $y^2 = 4\beta^2 + \frac{k^2}{p^2}x^2$ and the ellipse $y^2 = 4\beta^2 - \frac{k^2}{q^2}x^2$, and then measuring off in these two curves respectively the ordinates which belong to the abscissæ, $k + \theta$ for the hyperbola, $k - \theta$ for the ellipse, we have the values $\sigma + \sigma'$ and $\sigma - \sigma'$, which determine the point on the curve. Considering k, p, q, β as disposable quantities, the conics may be any ellipse and hyperbola whatever, having a pair of vertices in common. The author then proceeded to draw the curve and point out some of its peculiarities.

Mr. T. Cotterill then gave an abstract of his paper "On the intersection of curves, and a collinear correspondence in certain réseaus," going into the discussion of the following theorem:—If the assemblage of all the points of intersection of two plane curves be said to form an "intersect," and a series of groups of points, called the first, second, third, &c., be taken on a plane curve of an order > 2, such that the points in every two successive groups form an *Intersect*; then the points in any odd and any even group, or in any number of odd and an equal number of even groups, also form an *Intersect*. Amongst other applications of this theorem, certain exceptions were pointed out in the laws laid down concerning the intersection of curves. Thus a system of 13 points can be found such that a quartic through 12 of the points must pass through the 13th, whilst the quartics through the 13 points do not intersect again in three fixed points, but any such quartic is cut by any other quartic of the system in three points collinear with a fixed point on the first quartic. Hence arises a correspondence of three collinear points similar to Geiser's correspondence in cubics through seven given points. The details of the correspondence, including certain envelopes given in the paper, refer to curves of any order.

Syro-Egyptian Society, June 7.—Mr. W. H. Black in the chair. Mr. Robert Hay, of Limplum, exhibited a large and unusually fine collection of Egyptian Antiquities, the property of his late father, author of "Views in Cairo," by whom they were collected between the years 1828-33. They consist chiefly of five classes of objects. Bronzes, terra cottas, vases, funereal remains, and amulets in precious stones, and porcelain, besides six large mummies with their outer cases more or less complete. Mr. Bonomi, who gave an explanatory lecture on the various antiquities, pointed out the following objects as being noteworthy either from their rarity or beauty.

1. A large and fine bronze figure of Khonso, twenty-six inches high (No. 32), partly overlaid with antimony, and enamelled with a white opaque pigment, to represent the mysterious garment of that divinity. The head, hands, and collar had been gilt, and the eyes, staff, and mens inserted, but these latter had been lost before it was obtained by its late owner. The workmanship of the statue is of the best Theban art, and is an admirable illustration of the great chemical knowledge possessed by the ancient Egyptians.

2. A small terra cotta statue of a Royal Scribe (706), habited in the costume of the nineteenth dynasty. The seed bag hangs over the right shoulder instead of the left as usual, and the crossed hands clasp on his breast a figure of a hawk with human head and expanded wings. This bird symbolised the soul in Egyptian theroglyphy, and a like figure is used in Psalm xi. 1. Unfortunately this statue has been much injured. A second and more perfect example in limestone (No. 159) was also exhibited. Both rare specimens.

3. Four statues, one in bronze, one in stone, and two in porcelain (Nos. 12, 116, 846), of the Great Theban Divinity, Amun Ra. These figures are of rare occurrence in any material, as about the reign of Amenophis III., the worship of Amun Ra was overthrown, and his name sedulously erased from all inscriptions throughout Egypt, even upon the top of the loftiest obelisks. In a later period, that of Ramesis II., however, the worship of this divinity was resumed, and his name again appears on the monuments.

4. A porcelain amulet (894), representing a human-headed scorpion, having the tail turned up over the back. The head of this figure was originally surmounted by a crown or head-dress. Exquisite finish, probably unique.

5. A wooden tablet (539) of the kind described by some writers as astronomical, but more probably a votive stete dedicated to Homs, and intended as a charm or mystical talisman against accidents, the evil eye, and malign influences generally.

6. Several staves (572) in hard wood having a projecting spur or branch at the top. These staves were carried by the priests in funeral processions, and for some unknown reason it was necessary that they should be furnished with a short projection at a certain angle near the upper extremity, for if this were wanting in this natural stick it was supplied by art; such a specimen so furnished (573) was also exhibited.

7. A small bronze figure of the Goddess Pasht holding a shield in her right hand, with the left extended.—The preceding formed only a part of the objects successively noticed by the lecturer. Many domestic articles, models, lucernæ and personal trinkets remained, which from the lateness of the hour could not further be commented upon. The explanations of Mr. Bonomi were afterwards supplemented by various remarks from Messrs. Cooper, Cull, Hewlett Ross, Williams, Mills, Christie, Drach, W. H. Black, and other gentlemen, and it was further announced by the chairman (Mr. W. H. Black) that a special meeting would be convened for the first Tuesday in July, when the drawings, MSS., and papyri of the late Mr. Hay would be exhibited, and also a collection of photographs lately sent from Syria by Dr. Cull, in illustration of the same. It may be gratifying to our antiquarian friends to know that by special permission of the Council of the S.-E.S., the collection may be viewed during this present month at their rooms, No. 22, Hart Street, W.C., between the hours of eleven and four, where all particulars respecting the destination of the antiquities may be obtained.

DUBLIN

Royal Irish Academy, June 13.—Rev. Professor Jellett, F.T.C.D., president, in the chair. The minutes of the previous meeting were read and confirmed. Dr. Sigerson, F.L.S., read a paper entitled "Further Researches on the Atmosphere." He showed that his former discoveries had been confirmed by later investigations, and proceeded to detail the results of his examination of "special atmospheres." His lecture was illustrated with large diagrams representing some of the objects discovered. In "iron factory" air he found carbon, ash, and iron. The iron was discovered to be hollow balls averaging one two-thousandth part of an inch in diameter, their shell being only one thirty-thousandth, and the iron was then found to be translucid. In "shirt factory" air there were found to be filaments of linen and cotton with minute eggs. The air of thrashing and oat-mills had fibres, fragments, starch grains, and spores. Scutch mills, from the character and quantity of the spongy, spiky dust and its effects, he declared to be human slaughter-houses. By a suggested alteration, the works could be kept free of the dust, and many lives saved. In the air of printing offices antimony was expected, and Dr Sullivan's analysis confirmed the expectation. It is, probably, present to an injurious extent in type-foundries. Stable air was shown to contain scales and hairs, and hair-dressers had a similar atmosphere. Smoke being microscopically examined, the tobacco-smoker's air was shown to contain globules of nicotine. He concluded by stating conclusions arrived at with regard to lung-functions and contagion. The results of Dr. Sigerson's investigations proved, as might be expected, that the air in special workshops contained floating in it particles of the *débris* of the different materials operated on in these particular localities. Some discussion followed, at the conclusion of which, on the motion of Prof. Sullivan, the paper was referred to the Council for publication. John P. Keane, C.E., Calcutta, and Hugh Leonard, Kylemore, were elected members of the Academy.

PARIS

Academy of Sciences, June 20.—M. R. Clausius presented a note on a quantity analogous to the potential and on a theorem relating to it. M. Bertrand communicated a note by M. G. Darroux on the surface of the centres of curvature of an algebraic surface.—A memoir was read by M. Maurice Lévy on the general equations of the internal movements of ductile solid bodies beyond the limits at which elasticity can restore them to their original state.—The following papers on subjects connected with physics were presented to the meeting:—On the variations of temperature produced by the mixture of two liquids, by M. Jamin, upon which M. Bussey made some remarks.—On the electrical effects produced by the contact of inoxidisable metals with acids and neutral and saturated saline solutions, and on capillary affinities, by M. Becquerel. The author describes the results obtained with wires of pure platinum and gold, treated as described in a former communication, but immersed in acid or saline fluids.—Determination of the terrestrial-magnetic intensity in absolute value, by MM. A. Cornu and J. Baille, presented by M. E. Becquerel, in which the authors describe a series of experiments made in accordance with the methods of Gauss and Weber.—Experimental researches upon the duration of the electric spark, by MM. Lucas and Cazin, also presented by M. E. Becquerel.—On the law of the points of congelation of saline solutions, by M. Güldberg.—A note by M. G. Rayet on the reversal of the two sodium lines in the spectrum of the light of a solar protuberance was presented by M. Delaunay.—M. Periseux communicated a note on the transit of Venus in 1874, containing a numerical correction of his former paper on this subject.—M. Delaunay presented a note by M. H. Tarry on the so-called showers of dust and blood. The author notices the storm phenomena preceding the showers of sand which fell in the south of Europe on the 10th and 24th March, 1869, and the 14th February, 1870, indicating that in each case a great barometric depression, accompanied by a violent wind storm, travelled from the north to the south of Europe, crossing into Africa, and returning thence laden with sand from the Sahara. He identifies the material deposited in these storms in all cases with the Sahara sand.—M. C. Dufour read a note relating to magnetic perturbations observed by Saussure at the Col du Géant before the great storm of 1788. M. H. Sainte Claire Deville communicated a note by M. C. Schlœsing on the precipitation of mud by very dilute alkaline solutions. The author stated that a very small quantity of a saline solution facilitates the deposition by water of earthy matter held in suspension by it, and that a deficiency of saline constituents is often the cause of water remaining muddy when standing in clearing tanks.—A note by M. Scheurer Kestner on the composition of crude soda and the loss of sodium caused by the adoption of Le Blanc's process was presented by M. Balard. The author noticed the chief compounds with which crude soda is contaminated, and stated as the result of his researches upon Le Blanc's method that in the fusion of crude soda there is no reduction of soda-salts into metallic sodium, and that the greater part of the loss experienced is due to the formation of insoluble compounds, and averages about 5 per cent.—M. Bertrand communicated a note by M. Rabuteau, on a new, simple, and rapid mode of quantitative determination of the ammoniacal salts, and on the reason why these salts can exist normally in the organism only in infinitesimal quantities. The author stated that chloride of soda prepared by pouring a solution of two parts of carbonate of soda into one part of chloride of lime contains an excess of carbonate and free soda, and that, by the aid of heat, this solution decomposes ammoniacal salts with evolution of nitrogen. From the amount of nitrogen evolved, the quantity of ammonia may be calculated. He considered that the alkalinity of the blood would enable it in like manner to decompose any ammoniacal salts contained in it.—A note on the tribromhydrines, by M. Berthelot, was presented by M. Bertrand, in which the author maintained the isomerism of those compounds in opposition to the opinion of M. Henry.—M. H. Sainte-Claire Deville communicated a note by M. Fontaine on the preparation of bibrominated ethylene, in which the author described a new method of obtaining that compound.—M. Wurtz presented a note on an aromatic glycol, by M. E. Grimaux.—An extract from a letter from M. Pasteur to Marshal Vaillant, describing the results obtained in breeding French races of silkworms, at Villa-Vicentina, was read.—M. C. Robin presented a note by M. Picot containing the results of some experimental researches upon suppurative inflammation and the passage of leucocytes through the walls of vessels.

June 27.—M. Serret presented a note by M. R. Hoppe on a corollary to a theorem of Mr. Crofton's; and a note by M. F. Lucas on some new properties of the potential function was communicated by M. Delaunay.—M. d'Abbadie presented a note by M. J. Hoüel on the selection of the angular unit, containing a further discussion of the question of the decimal division of the quadrant or the circle, and supporting the former as the unit. M. Yvon Villarceau remarked upon this paper, and maintained that the decimal division of the circle is preferable to that of the quadrant.—M. H. Sainte-Claire Deville read a paper entitled "Observations with regard to a Note by M. Jamin on the Variations of Temperature produced by the mixture of two Liquids."—A note by M. J. Chautard on the direction of the currents induced by means of electrical discharges was read.—A letter from Mr. C. K. Akin, claiming priority in the method of calorimetry employed by M. Jamin and ascribed to M. Pfaundler, was read; and M. Neyreneuf presented a note on the phenomena of electrical condensation.—A paper by M. Martin de Brettes on the determination of the thickness of iron casing that can be traversed by a projectile of which the weight, the calibre, and the striking velocity are known, was read, indicating the formulas to be employed, and giving a table of experimental results contrasted with those obtained by calculation.—A paper by Mr. J. N. Lockyer on the last eclipse of the sun observed in the United States was read.—The following papers on subjects connected with chemistry was communicated:—Investigations on some new derivations of triæthylphosphine, by MM. A. Cahours and H. Gal; letters by M. H. Bouilhet and Klein on the deposition of nickel by galvanism, presented by M. Dumas; on a new method of preparation of the chlorobrominated organic compounds by M. Henry; on silicopropionic acid by MM. Friedel and Ladenburg, upon which MM. Dumas and Thenard made some remarks; and a note on phospho-platinic compounds by M. Schützenberger.—A note by M. Montagna was read noticing the occurrence of organic remains in rocks regarded as of igneous origin; and M. de Verneuil made some remarks on a memoir by M. Dieulafait on the zone of *Avicula contorta*, and the Infralias in the south and south-east of France.—M. de Clos communicated a note on the germination (or twin growth) of the whorls of floral axes in the Alismaceæ.—The remaining papers read need no notice, except one, of which unfortunately the title only is given us, in which M. Tremblay suggested *a means of terminating the present drought.*

THURSDAY, JULY 14, 1870

THE UNION OF THE ELEMENTARY TEACHING OF SCIENCE AND MATHEMATICS

ATTENTION is being more and more given to the teaching of science as a means of education. The object of education may be regarded as being to help people to think for themselves; and our duty in practically educating people is two-fold; we must supply them both with the materials for thought and with the method of thinking. It is in this latter respect that the scientific education which has as yet chiefly been given appears to us to have been somewhat deficient. Yet this is the most important part; for materials for thought are supplied by nature itself, whereas the method of scientific thought and reasoning is the result of the world's progress, and to inculcate that method ought to be our chief aim. The excellence of science as a means of teaching people how to think, consists in two things: first, that the facts with which it has to deal are real tangible things, and secondly that the method of reasoning which it applies to these facts is accurate; for if, in any part of science, the accuracy of mathematical reasoning is not attained, at least we can always put down our finger distinctly on the places where it is and where it is not attained. Now the error which has been made, and which is constantly being made, in the teaching of science throughout the country, is that these accurate methods of reasoning, and these tangible facts, have been separated from one another. In our boys' schools and elsewhere (with very few exceptions), mathematics are taught wholly as applied to hypothetical cases, if even so much as that. They are thus the driest bones of method, or like a mill grinding without any corn in it. A man who learns method in this way is like a man who learns anatomy from diagrams and not from the human body itself. On the other hand the facts with which science has to deal are, with very few exceptions, almost everywhere brought forward as isolated facts, or their connection is treated in such a way that the true scientific accuracy of reasoning, by which that connection is demonstrated, is either omitted, or receives an altogether unimportant place. In the more advanced walks of science and mathematics the University of Cambridge is perhaps primarily to blame for this separation between the scientific method and the facts of science. But that University is rapidly making amends for its previous errors, and is, perhaps, pursuing as direct a course as possible towards the reunion of these two. Perhaps it may be that our teachers of schools and others, coming mostly from the University, have carried this unfair dichotomy into their own teaching. The fact is that we are only just beginning to awake all through the country to the immense benefit to be gained from scientific teaching, and we could not expect that, until this awakening had occurred, science should have been properly taught. At the University there are certainly the most unbounded facilities for the true teaching of science, in the maturer minds and more advanced mathematical acquirements of our students; but at the same time, the problem of uniting at schools the study of mathematics with that of the facts of nature is exactly the same problem. It is often objected, both by those engaged in teaching and by others, that an extensive knowledge of mathematics is required before we can apply it to Physical Science. This belief is perhaps one of the things which stand most in the way of the true teaching of science; but the belief is entirely erroneous. Of course a person must first acquire a knowledge of the technical forms of mathematical expressions which are to be used; but it has been found that at the very earliest stages of the learning of any mathematical subject, the application of it to the facts of nature may be taught. In this way a new life is given to the whole study, and a comprehension of it is attained, which is, at least in most cases, otherwise quite unattainable. Let us take an instance.

The subject called "Variation" in Algebra is exceedingly uninteresting as it is usually taught; a sharp boy or girl regards it as, for the most part, but a poor and unnecessary substitute for the rules of proportion, and the applications of the rules for variation are learned from such cases and exercises as have no connection with any subject of interest. Yet, as every one knows, in every part of physical science the facts which are eventually to take the form of equations present themselves as problems in variation; as, for instance, "Ohm's laws." It has been observed that where the subject of electricity is taught (and we are happy to say that it is now sometimes taught to boys and girls) such a matter as the establishment of Ohm's laws is left out; if taught they are taught as results which have been arrived at, as of immense importance of course, but, at the same time, the train of reasoning whereby they are demonstrated is omitted, just *because* it involves the use of the rules of variation. And so indeed it will always be, so long as the plan is adopted of teaching people these and similar rules as abstract things. For when rules so taught come to be applied, the mind has to fit itself first into quite a new way of looking at things, and waste of both time and trouble is the result. On the contrary, it has been found that a child whose knowledge of algebra extends only to the elementary rules, may be successfully introduced to the subject of variation by an experimental demonstration of Ohm's laws. By this means both subjects are much better understood, and the child feels himself in possession of quite a new power, whereby not only the intellectual, but also the moral benefits resulting from education are intensified. This is only an individual example, but in all cases it seems clear that the teaching of the rules of mathematics and of the facts of nature should be, and can be, even in the most elementary instances, so adapted as to go hand in hand. An opportune and careful assistance enables the pupil to elicit for himself these rules as the most distinct form of expression of the facts of nature, and these rules enable him to trace the connection between these facts. The elementary parts of physical science teem with opportunities for the elucidation and application of the elementary rules of mathematics, the full force of which is not rightly understood until they are applied.

A question which continually arises in the mind of an intelligent pupil is: "How did this or that piece of mathematics come to be used?" This is a question the need of which ought not to exist; for the pupil should be introduced to each piece of mathematics by the process of, as it were, himself discovering that it is the proper mode of dealing with some natural fact. By this method of teaching, that best of all faculties, originality, is fostered, whereby we mean not the making of new discoveries, but the habit of taking our own view of everything; in other words, the habit of independent thought, which habit is the nurse of Freedom. It is precisely because of its immense power of fostering this habit that we believe the teaching of science properly conducted is such a very desirable part of education. The difficulty of carrying out the joint teaching of the facts of science and the methods of mathematics, lies chiefly in the difficulty of getting men who are able to do it, that is to say, men who have a sufficient acquaintance with both subjects. This is the great temporary drawback to the spread of true scientific education. But as soon as the true character of that education is recognised, this drawback will only be temporary. Here it is, however, that the progress of these ideas at the University is so much to be desired. And here it is that the University is, let us hope, hastening to confer a great benefit on the country, by providing, for the teaching of others, men whose education has itself been carried out on this principle. This is one of the reasons for which we hope that there will be no long delay in the establishment of lectures there of an experimental nature on Physical Science. The benefit conferred by these, however, will not be complete, until it is arranged that the taking of a mathematical degree shall have ensured the knowledge of such subjects; and the possession of a certificate of attendance on some such course of lectures might well be imposed as a necessary preliminary to taking a degree with mathematical honours. Indeed we may hope that the day may not be far distant when some experimental knowledge of Physical Science will be demanded from all Cambridge students at the "little-go," along with the present Latin, Greek, and Mathematics, for this, more than anything else, would conduce to that which is now so eminently desirable—the existence of a body of persons able to carry out this joint teaching.

FORMS OF ANIMAL LIFE

Forms of Animal Life; being Outlines of Zoological Classification, based upon Anatomical Investigation, and illustrated by Descriptions of Specimens and of Figures. By George Rolleston, D.M., F.R.S., Linacre Professor of Anatomy and Physiology in the University of Oxford. (Oxford: Macmillan and Co., 1870; Clarendon Press Series.) II.

THE second part of this work consists of elaborate descriptions of fifty preparations in the New Museum at Oxford, designed to illustrate some of the typical specimens of the several animal classes. Thus, among Vertebrata, we have a dissection of the common rat, the skeleton of the same, separate vertebræ of the rabbit, the dissection and the skeleton of a pigeon, the bones of the head and trunk of a fowl, a dissection of the common English snake, vertebræ of a python, dissections and skeletons of a frog and a perch, and vertebræ of a cod.

These descriptions will no doubt be exceedingly useful to the author's pupils, but for others statements that "a black bristle has been passed under the aorta," or "a slip of blue paper under a fascicle of one of these muscles" do not afford much help. Moreover, there is a singular absence of directions how the student is to make these preparations for himself; directions which no one could give better than Professor Rolleston. It would surely have been a more desirable course to print this second part separately in the Museum catalogue; and, instead of mere descriptions of plates, drawn from ready-made dissections, to have given a full account of how first to catch, then to kill, and then to dissect and preserve the several animals mentioned in the third part of the book. The satisfactory way in which careful methods of dissection will preserve the whole of an animal for demonstration was lately well shown by the Curator of the Hunterian Museum, who prepared from a single very poor specimen of *Proteles cristatus* the complete skeleton (articulated so as to allow of each bone being removed without disturbing the rest), the stuffed skin, and all the important viscera. Now, methods of dissection of the so-called lower animals, are just what students of comparative anatomy want; and monographs of the anatomy of a single species like those of Bojanus, or of Krause, are rare even in Germany. Therefore knowing the admirable way in which practical zootomy is taught by Professor Rolleston, we had hoped that, following out his motto παντὸς προσθεῖναι τὸ ἐλλεῖπον, he would have described the steps of the several dissections so that other students might profit by his experience. The plates in the present work would serve very well to illustrate such a manual of dissection, especially if aided by such rough diagrams of relations of parts as every lecturer makes for himself on the black board.

Most of the plates in the third part are copied from actual preparations, and are evidently done with great pains; but it would have been well if some notion of the scale on which they are drawn had been added. The bibliography at the end of each description in Parts II. and III. is very valuable; indeed references are fully given throughout the book.

In the account of the dissection of *Helix pomatia* (pp. 48–54), we look with interest for any new facts as to the existence of a capillary systemic as well as pulmonary circulation in the Gasteropoda; since it has been stated that Mr. Robertson (who prepared all the specimens described) succeeded in demonstrating by injections that the supposed systemic lacunæ are only due to extravasation. This, however, appears not to be the case. We may particularly recommend the account given both of the shell and the soft parts of *Anodonta cygnea* (pp. 54-66, and also the description of Pl. V.), and the comparison with it of *Ascidia affinis* which follows. But perhaps the most valuable description is that of *Astacus fluviatilis* (pp. 90–119, and 205–210*), and especially three tables, of which the first compares the post-oral ganglia in *Astacus*, *Scorpio* and *Sphinx*, both at an early and at the adult period; while the second makes a similar comparison between the same ganglia in the *Amphipoda*, *Isopoda*, and *Orthoptera* (an order of insects which Prof. Rolleston regards as the least differentiated, and approaching nearest to Crustacea); and the third gives a view of the homologies of all the post-antennary segments and appendages in the four Arthropod classes. The views of Prof. Huxley are followed where he differs from M. Milne-Edwards, and the grounds of the several comparisons are clearly stated.

* In Pl. VII. it ought to have been noted that the longitudinal division of the body is not quite complete, so that the *left* eye, antenna and antennule, are seen—all the other appendages belonging to the *right* side.

The Entozoa are illustrated by the *Coenurus* of the rabbit's muscle, which is regarded as probably of "the same species as the one individuals from which are, when in the cystic state, lodged usually in the brain of the sheep, and are the cause of the disease commonly known as the 'sturdy,' 'gid,' 'staggers,' or 'turnsick'" (p. 136). So that *C. cuniculi* is identical with *C. cerebralis.* There are also some diagrams of parts of Tænia in the cestoid state (pp. 246-252), from Leuckart and Van Beneden, with descriptions.

Several new terms are introduced in this work, and most of them are likely to be useful additions to nomenclature. Among them are the words "proctuchous" and "aproctous," which we have only seen before used to distinguish the *Turbellaria* with an anus from those without one. Would it not be possible to substitute *Brachionopoda* for the barbarous word "Brachiopoda," which is moreover too near to "Branchiopoda?" Several terms in common use are given by Dr. Rolleston in an improved form; and we think him quite justified in substituting *Myriopodia* for Myriapoda, *Annulata* for Annelida (which is only a pseudo-classical form of "Les Annelides," the name invented by Lamarck), and *Hedriophthalmata* for Edriophthalmata —though if this last change be made, it will be as well to write "*Hedræophthalma*," since the root must be ἑδραῖος, not the doubtful diminutive ἕδριον, and the analogy of μονόφθαλμος, μυριόφθαλμος points out the true form of the termination. In the same way the word *Echinodermata* (which was first correctly applied by Stein to the *shells* of Echini) and *Pachydermata* ought to be written Echinoderma and Pachyderma, especially as the latter form is actually used by Aristotle. But there are probably too many words of this termination for the change to be easily accomplished. Useless synonyms, however, ought undoubtedly to be abandoned; such troublesome words, for instance, as Actinozoa, Ascidioidea, and Bryozoa, ought to yield to *Anthozoa*, *Tunicata*, and *Polyzoa*, for reasons of convenience, euphony, and priority.

The student will find it useful to note the following errata, in addition to those indicated in the book itself.

P. xiv. *monophydont* for *monophyodont* and *Montremata* for *Monotremata;* p. li., *furculum* for *furcula*, repeated p. 21 *bis* and p. 22; p. ciii., *classes Brachiopoda* for *class Brachiopoda;* p. 21, *obtusator* for *obturator;* p. 25, *Wirbel thiere* for *Wirbelthiere;* p. 35, *Körperban* for *Körperbau;* p. 78, *differs from the imago* for *differs from the larva;* p. 136, and again pp. 241 and 251, *Caenurus* for *Coenurus;* p. 160, *coenosarc* for *coenosarc;* p. 224, *two sets of them and two rays respectively* for *two sets of three, &c.;* p. 252, *Thudichen* for *Thudichum;* and, in the index, *Vesicular* should read *Vesiculae*, while the reference to Prof. Turner will be found at p. 1. of the second part instead of p. i. of the Introduction. Lastly, at p. 251, line 10 from the bottom of the page, the figure 6 is misprinted for the letter *b*.

It is much to be hoped that a second edition of this thorough and painstaking work will soon be called for; since nothing would better prove the increased number of serious zoologists in this country. Should its learned author then see fit to unite the second and third parts together, and to add somewhat full directions for dissection, I venture to think that the book will be made even more useful than it already is.

P. H. PYE-SMITH

NEW ATLASES

The Complete Atlas of Modern, Classical, and Celestial Maps, together with Plans of the principal Cities of the World, constructed and engraved on steel under the superintendence of the Society for the Diffusion of Useful Knowledge, and including all the recent geographical discoveries, compiled from the latest and most authentic sources. Accompanied by alphabetical indexes to the modern and classical maps. 218 maps and plans.

The Family Atlas, containing 80 Maps, constructed by eminent Geographers, and engraved on steel under the superintendence of the Society for the Diffusion of Useful Knowledge, including the Geological Map of England and Wales, by Sir R. I. Murchison, F.R.S.; the Star Maps, by Sir John Lubbock, Bart., F.R.S.; and the Plans of London and Paris, with the new discoveries and other improvements to the latest date, and an Alphabetical Index.

The Cyclopædian, or Atlas of General Maps, with an Index of the Principal Places in the World. 39 maps.

(London: Edward Stanford, 6 & 7, Charing Cross. 1870.)

AT the present time not a week passes which does not more and more enforce the necessity of everyone of us having an atlas of some sort or another to refer to, and, in fact, it may be said that in these days of rapid locomotion and intercommunication with every part of the planet, an atlas is the corner-stone of a library, even if that library otherwise consist merely of a Dictionary and a Blue Book, Imperial Calendar, or Post-office Directory.

Take the last six months. We have all of us been burning to know the ins and outs of that part of Africa, so far as they have been mapped, which we hope that Livingstone is still exploring for us. The Suez Canal has not only, to the amazement of school boys, made Africa an island as well as a continent; but children of a larger growth have had to talk about Port Saïd, the Bitter Lakes, and the Sweet Water Canal, thereby opening up a new region of minute geography; while the Pacific Railroad, now a *fait accompli*, has carried us at once into a part of the world about which the majority of us had thought but little; and we might easily go on multiplying other instances.

Geography, in fact, is now not only "one of the eyes of history," but it is the "eye" of every-day life among all Anglo-Saxon communities; and from this point of view it is satisfactory to see our foremost geographers and purveyors of maps keeping pace with the times, including "all the recent discoveries" in their publications, and bringing this very important information fairly within the reach of all. Let us add, that it is also satisfactory to see them little by little approaching the German standard of map-making, which, to speak candidly, they have not all reached.

We shall clear the ground for what we have to say of the atlases now under notice, if we state that the maps in all of them belong to the series brought out some time ago by the Society for the Diffusion of Useful Knowledge; that the two first on our list are of the size of the maps, and are for the library, while the third contains the maps folded, and will suit either a school-boy or a family of small geographical requirements. The Complete Atlas differs from the Family one in having classical maps and a large number of plans of cities; the modern maps being pretty much the same in both; both also contain maps of the stars. Sir Roderick Murchison's geological map of England and Wales, however, is to be found in the Family Atlas only. All of them contain a most valuable index of places, so that we have on the whole a very practical gradation to suit all requirements, the *quality* being the same but the *quantity* varying.

There is one very admirable point in the arrangement of the Complete Atlas which at the same time reminds us that it is not so complete as we are sure Mr. Stanford will make some edition of it in the more or less remote future. Side by side with the modern (politically divided) map we have the ancient (politically divided) map of the same area, and in this point the Complete Atlas will commend itself to all scholars; but we miss very much indeed the physical maps of the larger areas, and in the interests of physical geography we feel bound to insist strongly on this point, because we are convinced that the importance of such maps to those who want a large atlas is becoming so great that it will not be borne that they shall be relegated to a separate volume.

By many, and those especially who are content with the modern world, the Family Atlas will commend itself by its index-like arrangement, by which the names of all the maps are visible down the side, and the sides of the foremost maps being cut away, any map may be at once turned to.

This much premised, we may state that we have examined the maps and plans very carefully, and find them as a rule as good as any English maps extant, and honestly brought down to date. Mr. Stanford deserves great credit for the admirable and careful way in which this has been done, and we say this the more strongly because we know the immense labour and expense involved in altering map plates from time to time. Of course, in some cases, it has been simply impossible to alter the plates, the alterations have been too great. Take for instance the plans of New York, extending to Forty-second Street only, and Boston, in which the waste space shown in the map, west of the public garden, is now covered with houses. In other cases all the care has been displayed in the detail map, the general map having escaped revision, or *vice versa; e.g.*, in the map of British North America, Russian America is retained, while in the general map it is correctly omitted; in the general map of Canada and the United States the chief town of Iowa is shown as Iowa City, while, in the detail map, Des Moines is correctly given. We could have wished too to see Patagonia, a time-honoured name, divided, as it really is, between the Argentine Republic and Chili; and we have an idea, too, that by an Order in Council, or some such terrible enactment, the "improper" name of Van Dieman's Land has been altered to Tasmania! We notice these points, not as blemishes by any means, but as indications of a more or less minute revision which we are sure Mr. Stanford would have otherwise undertaken, of a collection of maps of which English geography may be proud.

OUR BOOK SHELF

Birds of Marlborough, being a Contribution to the Ornithology of the District. By Everard F. im Thurn. (12mo. pp. 117. Marlborough and London, 1870.)

THIS unpretending little book affords an additional piece of evidence, if more were needed, that science in some form or other is making its way into our schools. A few years ago it was well remarked by one who had given no small attention to the matter, that the relations of the universities and public schools, as regarded science, formed a "vicious circle"—on the one hand the public schools demurred to its encouragement because it did not "pay" their pupils when they reached the university, and on the other the universities hesitated about rewarding scientific studies because they were pursued by intellects comparatively inferior to those which were devoted to the older branches of learning. This state of things clearly admitted of a remedy; either great power of itself could make the first step; but it was certainly the duty of the universities to take the lead in moving. It must depend on them, and on them alone, to alter and improve the whole higher education of our countrymen, for the curriculum of any public school is almost exclusively prepared with reference to the requirements of the universities and the rewards for proficiency that they offer.* They have but to declare that their emoluments and privileges are accessible to excellence in every branch of human knowledge, instead of confining these encouragements to some very few alone, and leave the public schools to respond to the call. With skilful gardeners these nurseries will speedily grow the plants required; the germs are already there, and under the sunny smiles of pedagogic favour and the golden rain of prizes, vigorous saplings will be transplanted to the Groves of Academe, there to hold their heads as high as their rivals from the primæval forests of classics and mathematics, and (may we say?) to be finally of greater utility.

If Mr. im Thurn's book, as might be expected from the performance of so youthful an author, does not contain any addition to science, it will, of course, be interesting to Marlburians as the work of one who has just ceased from being a schoolboy; but its chief value lies in the fact of its indicating the presence of the promising germs we have mentioned above, of the excellent forcing pit found in the Marlborough College Natural History Society, and of the skilful gardener, Mr. T. A. Preston.

Gymnastics for Ladies. Madame Brenner.

ALTHOUGH many of our large towns are now provided with gymnasiums at which ladies' classes have been established, the subject is but little appreciated, especially, in some more important cases, among the ladies themselves. There can be no doubt that for growing girls a large airy room, provided with suitable apparatus, and where a loose easy dress is a necessary condition, must be advantageous, if the exercises performed are such as to induce emulation without over-exertion. When we consider at how much earlier an age "romping" is prohibited to girls than to boys, and how little there is in the routine of a girl's life to correspond to the cricket and rowing which form the best part of her brother's recreations, we think the fact offers a very probable explanation of the increasing languor and delicacy of the ladies of the period. Breadmaking and other manual duties are being superseded by reading and preparing for examinations, and we must, therefore, look to artificial means to preserve a just balance between mental and physical development.

Madame Brenner's book is little more than an advertisement of her class in Bruton Street, being a description of those exercises which she teaches, enlivened by rather severe criticisms of those which others teach. Still we hope her book will find many readers, as the graceful

* See Rep. Brit. Assoc. Dundee, p. xliv.

illustrations, the strains of lively music which we are told accompany every movement, and, above all, the repeated assurance that the ladies need do no more than they like, will all tend to persuade parents and daughters that gymnastics are very pleasant and desirable.

On Eozoön Canadense. By Professors King and Rowney. 8vo. (Dublin, 1870.)

THIS reprint from the Proceedings of the Royal Irish Academy, treats of a controverted subject of considerable interest to geologists and zoologists, namely, the nature of certain Canadian and other serpentinous limestones in which Logan, Dawson, Sterry Hunt, Carpenter, Jones, Gümbel, and others believe they find definite traces of a foraminifer known as *Eozoön*. Great difference of opinion on the subject under notice has been expressed during discussions before learned societies and in memoirs written by geologists, some seeing under the microscope good proofs of the presence of foraminiferal structure; and these observers are mainly rhizopodists well acquainted with the peculiar structures of shelled protozoa, others finding nothing but inorganic fibres, globules, flocculi, &c., of mineral matter in both the Canadian and any other similar serpentinous marbles. Among the latter disputants are Doctors King and Rowney; and in the paper before us there are some new descriptions and figures of specimens illustrative of the structure of certain ophitic rocks from different countries, and likely to be of use to "eozoönal" students, enlarging their field of observation, and aiding them, perhaps, in arriving at definite conclusions. The figures, however, are little better than diagrams, and cannot help the student much. The paper is largely composed of criticisms on the researches and remarks of others, in a highly disputatious form, and not enriched with anything new to those who have thoroughly studied the matter, either mineralogically or from a zoological point of view. The following important facts do not appear to be recognised by the authors: first, that ophites, on the one hand, may not be really "eozoönal" and yet have mineral structure resembling in one point or another what occurs in *Eozoön*; secondly, that true eozoönal rock is often so greatly crumpled up in its metamorphic state, that patches only of the organic structure are found here and there amongst the somewhat similar ophitic mass of granules and fibres.

Die Ophthalmologische Physik, und ihre Anwendung auf die Praxis. Von Dr. Hugo Gerold, of Giessen. Part II. (Vienna, 1870. London: Williams and Norgate.)

THE advances in the department of Ophthalmology have of late years been so rapid and important, that either thoroughly-revised editions of the standard works or altogether new books have become a sheer necessity. The volume before us comes under the latter category, and is the work of a gentleman well known as an able physicist. The present part is occupied with the Dioptrics of the Eye; the defects in it that are due to spherical and chromatic aberration; the terminology employed to indicate the different functional relations of the several parts to one another and to light, as æquatorial, median, and sagittal planes, axes, visual lines, field of vision, angle of elevation, &c.; the principles of perspective and of the construction of the microscope, the ophthalmoscopic investigation of the eye, and the adaptation of convex and concave lenses for hypermetropia or myopia, and lastly, a section on light and colour. The parts we have read appear to be clearly and intelligibly given, and with something like French method and order. The mathematical formulæ introduced are not beyond the comprehension of an ordinary well-instructed reader, and the diagrams are numerous (123 in number) and instructive.

H. P.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Prof. Pritchard and Mr. Proctor

IT has been pointed out to me that Prof. Pritchard, engaged as he is in many important avocations, may quite unwittingly have misjudged my treatise on the Plurality of Worlds. I readily (eagerly) admit this, and also that, in this case, I owe the esteemed Savilian professor an apology for suggesting that he has intentionally wronged me.

The matter is now reduced to a simple issue. I have submitted considerations which are sufficient to convince Prof. Pritchard that his critique is not just. If he withdraws his unfavourable comments, as resulting from accidental misconception, I shall be bound to apologise for too hastily charging him with deliberate unfairness. If he will not, I cannot truthfully withdraw my objections. I will not endure to be represented as speaking severely (and by inference unfairly) of men for whom I have (and have expressed) a most sincere and unqualified admiration—of such men, to wit, as the Herschels, Tyndall, Lassell, Balfour Stewart, and Sir W. Thomson.

RICHARD A. PROCTOR

Whence Come Meteorites?

I HAVE read, with great interest, in the number of June 2nd of your journal the article which Mr. N. S. Maskelyne has devoted to the examination of my theory on the Origin of Meteorites. I request permission to offer some observations on the criticisms of that learned mineralogist.

Although Mr. Maskelyne concludes by saying that, in his opinion, I have not attained the end which I had proposed to myself, I will attempt to show that my system has, in fact, perfectly resisted his attacks.

In truth, the views I have been led to take on the subject of meteorites are not by any means a simple fruit of my imagination. I have been led to them by the observations of material facts easy of verification; and it is only in the background, so to speak, that I have brought under consideration different consequences, which may certainly be matter for discussion. Now, in Mr. Maskelyne's argument, he has given the place of honour to these secondary considerations, whilst he has left the real substance of the question completely in the shade. A few lines will suffice to justify my assertion.

The chemical and mineralogical study of the specimens which compose the rich collections of meteorites at the Museum of the Jardin des Plantes has made me acquainted with *polygenic* masses—that is to say, masses formed of angular fragments soldered together, but possessing each one such decidedly separate characters that it is impossible to suppose that they were originally produced in the forms and in the relative positions which they present at the present day. These clastic meteorites had been previously studied; but not, as far as I am aware, from the point of view at which I have placed myself.

From the studies and experiments I have made on this subject results the indubitable fact that the fragments, the union of which constitutes various clastic meteorites are, each one, completely identical with well-known monogenic meteorites. It is thus, that the clastic meteorite of St. Mesmin (May 30, 1866) contains angular fragments rigorously the same in every respect as those which would be produced by breaking up the meteorite of Lucé (Sept. 30, 1768); fragments soldered together by a dark coloured cement exactly similar to the substance which forms the principal mass of the stone of Limerick (Sept. 30, 1813). It is thus also that in the same cement, the meteorite of Canellas (May 14, 1861), contains fragments of a rock impossible to distinguish from that of which the mass of Montrejeau (Dec. 9, 1858) is a specimen.

How is it possible to understand these positive facts without having recourse to the explanation, so evidently true of terrestrial fragments? For fragments of two distinct rocks to be found associated in one clastic mass, it is absolutely necessary that these two rocks should come from a region where they were in connection. Thus, on one hand, the rocks of Lucé and of Limerick were in connection; thus, on the other hand, the rocks of Montrejeau and Limerick were in connection; then, in conclusion, the rocks of Lucé and of Montrejeau were in connection.

By the side of this first assemblage of facts, of which the meaning seems to me not doubtful, I find another of at least equal importance—that of meteoric rocks evidently eruptive.

The meteoric iron recently discovered in the cordillera of Deesa, in Chili, having been submitted by me to a careful analysis, both chemical and mineralogical, appeared to me clearly to be formed from the mixture of two meteoric rocks, known, each of them, by masses of which they are entirely constituted. The one, stony and black, fell at Sétif, Algeria (June 9, 1867); the other, metallic, constitutes the mass of iron found in 1828 at Caille, in the south of France. Besides this, the metallic portion of the iron of Deesa, in which the black angular fragments are encrusted, has manifestly preserved the character assumed by the iron of Caille when it is subjected to fusion, so that the mode of formation of the Chilian mass cannot be considered doubtful. We must believe that on a globe, large enough to have been the seat of considerable pressure, masses of iron from Caille, still melted, were injected into superposed layers of Sétif rock so as to give birth to dykes, identical, except in their mineralogical nature, with those which the crust of the earth everywhere presents to our view.

These two orders of facts, which seem to me indisputable, being admitted, there remains to explain how fragments of polygenic conglomerates, or of dykes, can wander through space, and here only it is that the hypothetic part of my work begins.

From what precedes the meteorites in question are, by definition, planetary fragments. It remains to learn how the rupture of the planet whence they come can have taken place. On this it is evidently impossible to argue with any certainty.

Nevertheless, it appears to me that several considerations may greatly facilitate a choice among the different explanations which present themselves to the mind.

In the first place the *unity of composition* of the solar system, mentioned by Mr. Maskelyne, is evident.

Secondly, it is manifest that in the same system there exists a perfect *unity of geological phenomena*.

Lastly, but this, perhaps, has less weight, it appears to me that we should have recourse to accidental causes to explain natural phenomena only when every other means is forbidden.

This said, I observe that without making any other hypothesis than that of Laplace, we arrive at the conclusion that the stars tend of themselves to become broken. The earth is cracked in all directions; these fissures, designated as *faults*, are known to everyone. Little by little, as they form, they become reunited by the injection of an internal melted cement. But if the supply of this cement failed, the molecular operation which has opened the faults would still continue its action to enlarge them; we observe this in the moon, which, far more advanced in refrigeration, manifests by its fissures a phenomenon hitherto unknown in our earth. Evidently if we suppose to have been formed at the same time as the moon, a much smaller globe, that globe will have arrived actually at a state of cold far more advanced than that of the moon; and the fissures, excessively multiplied, and increased in depth and in width, may have finished by reducing the globe into separate fragments.

We have no positive proofs that such events have really happened, but is it not a very simple hypothesis to admit that meteorites, which bear so evidently the impress of a detritic character, may have had such an origin?

It is very probable that once parted from one another, the fragments are scattered along the orbit, and it is evident that they will tend progressively to approach the central star, so as to finish by falling on its surface under the form of meteorites.

Now, whether these fragments have been sorted or whether they have not, whether this sorting, if it exists, be or be not in accordance with that which the facts of observation have seemed to point out to me; I consider the question as entirely secondary as regards the general theory, and I request permission, in order to keep within the limits of the present discussion, to lay it absolutely aside for the present. I will simply repeat, in concluding this note, already somewhat long, that positive facts alone have served as the basis of my theory, and that the different circumstances on which my opponent has so learnedly insisted, possess for me but a secondary importance.

At the same time, I sincerely congratulate myself in the fact that my work has had the good fortune to fix the attention of a scientific observer so well placed as Mr. Maskelyne for submitting the mineralogical and lithological part of it to a severe verification.

23, rue de Vaugirard, à Paris

Monographs of M. Michel Chasles

PAR une lettre inséréee dans le No. 36 de NATURE, page 190, M. C. Ingleby fait appel aux lecteurs de votre Revue pour obtenir quelques renseignements au sujet de "l'Aperçu historique" de M. Chasles, imprimé à Bruxelles en 1837. Le travail, qui porte pour titre exact : "Aperçu historique sur l'origine et le développement des méthodes en géométrie, particulièrement de celles qui se rapportent a la géométrie moderne," a été publié par l'Académie royale des sciences de Belgique dans le tome xi. de ses "Mémoires couronnés et des savants étrangers" (in 4to.), et il est très-difficile aujourd'hui de s'en procurer des exemplaires. Toutefois, M. Ingleby pourra s'adresser, pour consulter ce mémoire, à la Société royale de Londres, qui doit certainement le posséder dans sa Bibliothéque. Voici d'ailleurs la liste des établissements scientifiques de Londres qui ont reçu cet ouvrage a l'époque de sa publication : Société royale, Société astronomique, Société royale de littérature, et Société linnéenne.

J'espère que ces details pourront être utiles à votre honorable correspondant.

Bruxelles, le 8 Juillet A. LANCASTER,
Attaché au Secrétariat de l'Académie royale des Sciences de Belgique

---

IN reply to Dr. Ingleby's note I may state that many papers by M. Chasles on various subjects in the history of Mathematics, are to be found in the volumes of the *Comptes Rendus* for 1837, onwards. His "Aperçu Historique" &c., originally appeared as a special volume of the Transactions of the Brussels Academy, but was sold as an independent work. It appeared in quarto, and was published in 1837. Like his "Traité de Géométrie Supérieure," it is very rare, and fetches an enormous price. Mr. Quaritch is, perhaps, the most likely bookseller in London to be able to procure it. The German translation by Sohncke is comparatively cheap, and may be readily obtained through Messrs. Williams and Norgate.

Torquay, July 9 G. E. DAY

The Specific Heat of Mixtures of Alcohol and Water

IN the report of the papers read at the Academy of Sciences, Paris, June 13, which appears in NATURE for June 30, it is stated that MM. Jamin and Amaury presented a note on the above subject, in which they point out, apparently as if it were something new, that the specific heat of some of these mixtures rises even above that of water.

Now, more than two years ago, March 26, 1868, we communicated a paper to the Royal Society giving the specific heat of various mixtures of alcohol and water, and drawing special attention to the remarkable fact that the specific heat of these mixtures is not only above the calculated mean specific heat, but that in all those of less strength than 36 per cent. of alcohol, it is higher than the specific heat of water itself. A knowledge of this fact should therefore be old by this time.

An abstract of our paper is printed in Proc. R. S., vol. xvi., p. 337. Subsequently we examined this and various other properties of similar mixtures more in detail, and communicated our results to the Royal Society in a second paper, an abstract of which is printed in Proc. R.S., vol. xvii., p. 333, and the paper in full in Phil. Trans. for 1869, Part II., p. 591.

The insertion of the above in the next number of your valuable journal will greatly oblige A. DUPRE & F. T. M. PAGE
Westminster Hospital, July 2

Geographical Prizes

HAVING been chiefly instrumental in causing prize medals to be offered by the Geographical Society for competition among the chief public schools, I do not like Mr. Wilson's letter in your last number to pass without comment.

Geography may be, to use his words, a subordinate branch of education, but I maintain that it is so only in the sense that it underlies a large part of liberal knowledge. It underlies the study of history. For example, I do not see how a boy could thoroughly understand Bible history without having acquired a very vivid conception of the geography of Palestine, and the same is true for all other histories, ancient and modern. It follows, as a matter of fact, that geography is incidentally taught to a considerable extent in schools, and I am sorry to say it is sometimes very ill-taught, as we learn from the reports of our examiners, but through some omission, not easily to be explained, if it be not the effect of a mere accident, geographical proficiency has never hitherto been adequately encouraged. Consequently, the Geographical Society has thought it right to step in to supply the needful encouragement. There is another good reason for the interference of the Society, in the fact that facilities of travel have rendered our interests much more cosmopolitan than formerly, while the public schools of the old-established type, have made no corresponding change in their curriculum. Mere youths now-a-days have exhausted the grand tour of two generations back, and a year or two of early manhood is often spent in America, Australia, and India, while books of travel load our library tables. It seems monstrous that a so-called liberal education should not qualify men to journey themselves, or to read the journeys of others, in an intelligent manner.

Mr. Wilson remarks, and his remark deserves respect, that the masters of Rugby were almost unanimous in rejecting the invitation of the Geographical Society, but I can fairly retort that other scholars no less practised in education and no less competent to decide, pronounced our system of prizes to be a valuable and much-needed institution.

It would be easy to write at great length in support of what we have done, and I might perhaps be expected to say something on the respective objects of the political and physical geography prizes, but I do not wish to provoke a discussion in your pages, because I am on the point of going abroad and should be unable to take further part in it. FRANCIS GALTON

"Kinetic" and "Transmutation"

1. WHEN, in 1864, I wrote for the *Reader* the history of the Baconian Philosophy of Heat, I found in use, in connection with the subject, the term "dynamical theory of heat," in English, which was employed as an equivalent for the expression "mechanische Wärmetheorie," current in German. The word "dynamical," already so vague from frequent abuse, corresponded but little, when used in its proper meaning, to the real intent of the theory in question; and the same remark applies, with at least equal force, to the word "mechanisch," even wider in its scope and as often misused. I was thus led to adopt the word "Kinetic," to supersede the above; and that in preference to the current word, "cinematic," which, in conjunction with "theory," would imply a tautology.

I am glad to see that Sir W. Thomson and Professor Tait, in their treatises on Natural Philosophy and on Heat, as well as in some remarkable papers on Atoms which have appeared in NATURE, frequently make use of the same word, "Kinetic," in connection with the theory of heat and of gases, as also in conjunction with "energy." Instead of the expression, "actual energy," originally introduced, I believe, by Mr. Rankine, Sir W. Thomson and Mr. Tait employ the term "Kinetic energy;" and from various motives, linguistic as well as strictly scientific, I venture to think that the original wording of Mr. Rankine in the case of "potential energy," should be likewise superseded, viz., by "dynamic energy."

2. In the *Philosophical Magazine*, I have been rated, indirectly, by Professor Challis, (for no mention is made of my name in connection with the subject), for having applied the word "transmutation" to rays, without recalling the fact of his having done so before me. I considered the expression "transmutation of rays" as the abbreviated and thoroughly English rendering of the words, "change of the refrangibility of rays, or light," used by Professor Stokes; and as such, requiring no authority but the precedent furnished by the existence of the analogous expression of "transmutation of matter." If, however, an authority had to be cited, it would have been Euler, in whose "Nova theoria lucis et colorum" (Opusc. var. argum.) the following passage occurs:—"Cum igitur a corporibus rubris radii tantum rubri, et a violaceis violacei ad nos pertingant, etiamsi radii albi in ea incidissent, manifestum est istam transmutationem a sola reflectione proficisci non posse."

As I have returned to this subject, I may be permitted to express my astonishment that Professor Challis, who thought it due to him that his name should be mentioned for being the author of the expression "transmutation of rays," should have on his part omitted, in speaking of the transmutation of Herschelic rays into Newtonic, a reference to my own share in the *res gestæ*. When I see the same thing being done in so widely circulated a treatise as that of Mr. Brooke on Natural Philosophy, and in one intended for even more popular reading, reproducing the teaching of the Polytechnic, I might think of entering a protest, if experience had not convinced me of its uselessness.

C. K. AKIN

Parturition of the Kangaroo

I BEG leave to call your attention to certain comments in your issue of the 23rd of June on the proceedings of the last meeting of the Royal Geological and Zoological Societies of Ireland. It is usual when parenthetical observations are made in any journal without the customary affix "Ed." to ascribe them to the printer's devil. Now, your devil, in commenting on an *imperfect* report of your Dublin correspondent, would lead your readers erroneously to infer that I had adopted the ideas which he has been pleased to call "absolute nonsense," and takes me to task for saying "that the actual passage of the fœtal kangaroo from the uterus to the pouch was not yet proved;" he himself stating that my remarks were "in contradiction to the facts observed by the late Earl of Derby's father or by the present Professor Owen." Now, a critic calling in question the words of others should be careful of his own. No facts on the subject were observed by the late Earl of Derby's father, and Professor Owen, after elaborate arrangements for the observation, states that "as parturition took place in the night, the mode of transmission to the pouch was not observed." (Phil. Trans. for 1834, p. 344.) There have been four observers in this matter especially worthy of being noticed:—(1) the keeper at the Zoological Gardens, Knowsley, who, according to Lord Derby's statement, saw the young kangaroo born, and that it was placed in the pouch by the paws of the mother (Proceedings of Zoological Society for 1833, p. 132); (2) Professor Owen, as referred to above; (3) Mr. E. G. Hill, who, at thirty yards' distance, saw the kangaroo with her mouth take up what he thought was a stone, open the pouch with her paws, and place it in the marsupium, and that he shot the animal and found a newly-born fœtus in the pouch (Proceedings of Zoological Society for 1867, p. 476); (4) M. Jules Verreaux, who is mentioned by M. E. Alix as having seen the kangaroo remove the fœtus from the vulva with her mouth, and place it in the pouch (Annals of Natural History for 1866, p. 316). These all differ as to the actual facts observed, and would seem sufficient to justify me in the statement I had made. That Professor Owen does not consider the question settled, may be inferred from his concluding observations on the subject, "whether the circumstance of the parturition is constant, viz, the dropping on the ground, or whether the fœtus may occasionally be received by the mouth from the vulva, I am disposed to regard as a matter for further observation; but the main fact of the conveyance of the fœtus to the pouch by means of the mouth may now be held as the more probable (at least the more usual, if not the constant) way in the genus Macropus" (Proceedings of Zoological Society for 1866, page 382). I refrain from any comments, but I thought it right to remonstrate against statements which I felt were injurious to me, to the Society to which I have the honour to belong, and to the advancement of science. JOHN BARKER, M.D.

Dublin, July 1

The Extinction of Stars

IF you will kindly permit an amateur to rush in where astronomers fear to tread, I shall be glad to offer a few remarks on the above subject.

The progress of science enables us to trace, with a probability almost amounting to certainty, the career of a star from its birth; from the most diffused condition of its parent nebula; through the stage of primary agglomeration when it shines as our sun; through the process of cooling into a dim and cloudy spheroid, such as Jupiter or our earth; until cold rules supreme, and the once glowing orb rolls on, barren as our moon.

But when we have reached this stage, we have by no means done with the star. It must continue on its course, and, though in obscurity, it must retain its momentum and its attractive force. Our sun will thus one day travel in darkness, attended by a cohort of funereal planets, and perpetual night will reign over the solar system. This result appears to be but a question of time, and we are, therefore, led to the consideration that many systems must, in all probability, be already extinct, and wandering unnoticed. But as extinction is a gradual process, there will be multitudes of stars in various stages of dimness, and the brilliancy of any orb, its "magnitude" in fact, will therefore depend on its age, quite as much as on its size or distance. On this view, Sir W. Herschel's method of "star gauging" cannot be relied on for a correct determination of the actual shape of the cluster called the "Milky Way," as instead of taking the average of brightness only, as an indication of the average of distance, we have to superadd the average of age. Now, the smaller the star, the more quickly will its light die out, and, therefore, the necessary extent of our galaxy is immensely reduced; in other words, it appears that while the space separating us from the nearer stars, for which parallax has been obtained, remains of course unchanged, the computed distances of those hitherto considered to be farthest off, will be much lessened, as there appears to be no reason for concluding that telescopic stars are necessarily more distant than bright ones for which we cannot obtain parallax, but simply that they are older, or smaller, or both, and therefore dimmer.

Mr. Proctor, in "Other Worlds than Ours," argues that as telescopes barely reach the outermost stars of our own cluster, therefore it is impossible that they should reach to and resolve clusters constituting other systems and lying at distances enormously greater, and therefore that the resolvable nebulæ must lie within our galaxy. If my idea that the stars of our cluster which the telescope shows with difficulty, are not distant but dim, be correct, Mr. Proctor's argument appears to lose its force.

It will be readily allowed that if the light of the stars be fading away, a vast number may have already become extinct, and that it is indeed possible that the orbs now visible may be but a small surviving remnant of far greater multitudes which once illumined the heavens. If our cluster then be much reduced in extent, and its constituents be largely increased in number, it would follow, I imagine, that the chances against collision would be much reduced, and it then becomes less difficult to conceive the possibility of such an event having occurred in the case of the recent outbreak in τ Coronæ Borealis, especially if it were caused by the unobserved approach of an extinct body. This outbreak is usually ascribed to a sudden conflagration of hydrogen, the star being, as Prof. Roscoe says, "on fire." But a star self-luminous surely must be always on fire, and if it contain hydrogen, that gas must be in a state of constant conflagration. The temporary brilliancy of the star seems rather such as would be occasioned by a collision with some comparatively small body, whose impact was yet sufficient to generate heat enough to accomplish its own disintegration and ignition. Let us suppose that collisions are possible, and that their frequency is merely a question of the chances. What would be the consequences of such an event? I imagine that they would depend chiefly on the relative momenta of the colliding bodies; that if one were very much larger than the other, and the velocities high, the temperature would be raised sufficiently to dissipate the smaller into gas, while merely heating, or possibly liquefying the larger. If the bodies were nearly of a size, and their momenta were great, possibly both would be reduced to a gaseous condition; in either case their tendency would be to form ultimately a body equal in weight to the sum of its two constituents. Either the larger body would annex the smaller, or, if both became nebulous, the fervid gases would radiate their heat and contract anew into a system possibly containing a sun and planets.

Again, supposing that two bodies approach each other in such a manner as to avoid a collision, that is, so that their mutual gravity causes them to leave their paths and revolve round each other, we should have the explanation of the existence of double, treble, multiple stars; we should also understand how it happens that some stars (Sirius, for instance,) are accompanied by non-luminous orbs. Also, it would seem that if extinct stars are really far more numerous than is generally supposed, the theory which regards the revolution of attendant dark bodies as one cause of the variability of certain stars, receives fresh support.

Thus, in the course of time, nebulæ would form suns, suns would grow cold, or, while yet glowing, would come into contact and combine with other suns, till gradually space would be peopled with suns, larger and larger, but less and less thickly strewn. Pursuing the idea, we arrive at a period when all the stars of each galaxy shall become agglomerated into one mighty globe—nay, when all these vast galactic suns shall come together and form one solitary orb, in which all the matter once scattered through space shall be collected, accomplishing its successive fates as a sun without a system—a world without a sun—a cold and naked ball.

EARDLEY MAITLAND

Why is the Horse Chestnut Tree so called?

DURING the spring this tree is the ornament and pride of our public and private parks. In "Woodland Gleanings" it is stated to be a native of the north of India, and is supposed to have been introduced into England about 1575.

Our observant forefathers have given it the very significant name of *Horse* Chestnut (*Castanea Caballina*),* to distinguish it from all other species of chestnuts. The *reason* for so doing I have never seen stated in print; but from the three specimens of cuttings from a branch of this tree which I enclose, it will be very manifest. All over its branches, at every bud, can be seen what at a glance will be taken for an exact conformation of the *foot of a horse*, exhibiting the hoof, the nails of the shoeing, the fetlock-joint, &c., in marvellous miniature, some, of course, better developed than others. This curious freak in nature's vegetable kingdom, has, no doubt, been the origin of our nomenclature of this tree; and it would be an interesting point of philological inquiry to ascertain *whether or not its native Asiatic name has incorporated or associated with it that of the horse?*

I write with the view of eliciting information on this point, and with the hope, too, that some of your botanical contributors will throw further light on this peculiarity.

EUGENE A. CONNELL

Fall of an Aerolite

A LETTER of the year 1628, "sent by Mr. John Hoskins, dwelling at Wantage, in Berkshire, to his son-in-law, Mr. Dawson, a gunsmith dwelling in the Minories without Aldgate," and preserved among Nehemiah Wallington's Historical Notices (i. 13) contains the following narration:—

"On Wednesday before Easter, being the ninth of April, about six of the clock, in the afternoon, there was such a noise in the air, and after such a strange manner, as the oldest man alive never heard the like. And it began as followeth:—First, as it were, one piece of ordnance went off alone. Then after that, a little distance, two more, and then they went as thick as ever I heard a volley of shot in all my life; and after that, as if it were the sound of a drum, to the amazement of me, your mother, and a hundred more besides; yet this was not all, but, as it is reported, there fell divers stones, but two is certain, in our knowledge. The one fell at Chalows, half a mile off, and the other at Barking, five miles off. Your mother was at the place where one of them fell knee deep, till it came at the very rock, and when it came at the hard rock it broke, and being weighed, all the pieces together, they weighed six-and-twenty pound. The other that was taken up in the other place weighed half a tod, 14 pound."

I do not know whether there may be any other record of this remarkable aerolite, so simply but graphically described. Is it not just possible that some of the fragments may yet be preserved in the neighbourhood of its fall? At any rate a search would involve but little trouble.

T. W. WEBB

ANDERSON'S UNIVERSITY

WE extract the following from the *Evening Citizen* (Glasgow) of June 22:—

"The annual meeting of the trustees of Anderson's University was held this afternoon within the institution. Mr. William Ewing, in the absence of the president, was called to the chair. In the annual report which was submitted, reference was made to the death of Dr. Penny in November last, and the appointment of a successor. Mr. Young, of Kelly, who had arranged to set aside 10,000 guineas for the endowment of a Chair of Technical Chemistry in connection with the University, had, it was stated, no further proposal to make, he leaving it to the trustees to make what alteration in the deed of trust they may think proper. Under these circumstances, the managers recommended that advertisements be issued for a successor to Dr. Penny; that the chair should in future be styled the Chair of Scientific Chemistry; and that in electing the professor power should be reserved to the trustees to create such other chair or chairs of Chemistry in connection with the University, and elect such additional professor or professors to fill said chairs as the trustees may see fit; and also to arrange and define, from time to time, the respective departments of the subject to which each professor, including the Professor of Scientific Chemistry, should devote himself. Regarding the mode of electing professors, the

* The scientific name of the horse-chestnut is *Æsculus hippocastanum* it has no relationship to the *Castanea*, or sweet chestnut.—[ED.]

managers recommended that no change should be made. The earlier practice was to appoint the professor only for a course of lectures, and upwards of fifty years ago a bye-law was passed that the election of a professor should be only for one session. With a few exceptions, the election of professors has been annual from that date down to the present time, and the power of not re-electing has been of great service, says the report, in the management of the University. Dr. Steven introduced a motion to abolish the annual election of professors. He spoke of the present system as most degrading. It struck at the root of the institution's claim to be a university; and while it was evidently contrary to the will of the founder, Dr. Anderson, he had heard of no case in which it had been of benefit. Mr. Kidston, secretary, remarked that many years ago it had been the means of causing the professors to pay up their rent. Dr. Steven said he had heard it remarked that the trustees might come to look upon security for rent as a qualification in their professors of more consequence than educational ability. The professors, he contended, should be elected *aut vitam aut culpam.*—Dr. Pirrie seconded the motion. An amendment was moved by Mr. M'Lelland for having no alteration in the present system. Dr. Adams supported the motion in a speech of some length, in which he characterised the annual election of professors as somewhat disreputable. The chairman recommended that no alteration should take place. All the other officials, he argued, were elected annually, and why not the professors? Dr. Weir asked an explanation of the paragraph in the report which stated that the system had been found to be of great service. Mr. Kidston, by way of reply, again instanced the refusal of the professors to pay rent. On a division, the amendment was carried by 35 as against 6. The meeting was proceeding to some routine business when our reporter left."

We had hoped that the trustees of Anderson's University would have made good use of the opportunity which exists at the present time, in consequence of the vacancy in the chair of Chemistry and of Mr. Young's munificent offer to endow a professorship of Practical Chemistry, to make some alterations in the status of the professors of the institution; but we seem doomed to disappointment. The professors are still to be appointed yearly, to give one course of lectures, and to have the privilege of paying rent for their laboratories and class-rooms in the meantime. The consequence of this will be that no chemist of eminence will be induced to undertake the duties of a post in which he will find himself on the same footing with *other officials*, doorkeepers, and laboratory man, we suppose; and we shall be much surprised if anyone will be found to apply himself solely to the duties of the appointment if he is to be liable to find himself turned out at the end of a year. The principal portion of his time must necessarily be devoted to commercial work and other means of obtaining a living, to the great detriment of scientific research, and certainly not to the credit of an institution which claims to be a university.

THE MICROSCOPE

Choice of a Microscope.—Medical and other students are at this time of the year purchasing a microscope with which to begin the investigation of animal and vegetable structures. Others who would wish to invest in an instrument are deterred by the expense on the one hand and by the fear of obtaining a worthless thing on the other. Too strong a protest cannot be made against the notions prevalent with regard to microscopes, and encouraged by most of the makers in this country. The handsome-looking instrument of great size, with its long tube and innumerable wheels, is not to be recommended to the would-be observer, even should he feel justified in the expenditure. The microscopes which are used in most of the German laboratories where so much thorough work is done (to the writer's knowledge in Prof. Stricker's and Prof. Rokitansky's laboratories at Vienna, in Prof. Schweigger Seidel's at Leipzig, and in Prof. Claude Bernard's at Paris), are the little instruments of Hartnack, which do not stand above ten inches high, with a simple but large stage without any movement, no rackwork to the tube, but a sliding motion and a fine adjustment. The instrument is used in the vertical position with complete comfort, and when liquid is on the stage, this position being necessary, it is of considerable advantage to have a small microscope over which one can easily bend the head. Large microscopes, with their complicated machinery, are made to suit the optician who sells them, and not for the convenience of the observer. Those who wish to get a microscope should insist either on having one of these small and handy instruments made, or order one from M. Verick or M. Hartnack in Paris. Such a body having been purchased at a very minimum of cost, a larger sum may be expended on the really essential part of the apparatus, namely, the lenses. And here it will be found of great advantage to have the tube of the microscope not more than three-and-a-half or four inches in length, for then the objectives of the continental makers can be used with the greatest advantage, though, with proper care as to the ocular or eye-piece, they may be used on our ordinary long-tubed awkward English microscope. It is almost incredible that the English makers of object-glasses continue to demand three, or even four, times the price for their lenses which foreign makers do for lenses in every respect as good. For two pounds an object-glass may be obtained of M. Verick or M. Hartnack, of Paris, No. 8, which is quite as good a glass and in some respects more pleasant to use than the one-eighth, for which English opticians demand eight guineas. Many persons anxious to work with the microscope are deterred by the price of really first-rate instruments in this country. What we urge upon them most earnestly is to purchase such a body with eye-piece as that described above—simple but strong and steady—for between two and three pounds, and to equip the instrument with the objectives of MM. Verick or Hartnack, say No. 2, No. 5, and No. 8, which can be obtained for another four pounds. We shall have occasion again to speak of the merits of English and foreign objectives, especially of the immersion object-glasses. At present we speak from personal experience, and desire to point out the convenience and cheapness of the small microscope-body, and the thorough excellence and immensely diminished cost of the French makers' object-glasses.

Cutting Sections of Tissues.—The method of "embedding" first practised by Stricker and Klebs is now extensively used in Germany, and is of very great assistance to the practical histologist. It consists simply in surrounding the object from which sections are desired, with either paraffin, stearine, or a mixture of wax and oil. This latter is preferred at Vienna by Prof. Stricker and Dr. Klein, his assistant, and can be obtained of the exact consistency which may be desired; usually equal parts are to be used. A little tray of paper is made, and some of the wax composition in a melted state is poured in. The object to be cut is then placed in the tray, and more composition added, till the object is thoroughly enclosed. When hard, sections of the mass can be cut, the advantage being in the case of thin laminæ or processes, that a complete support is offered by the surrounding composition, and a uniformly thin cutting may be obtained. For some purposes the microtome of Dr. Ranvier, of Paris, is very useful: it is similar to one recently brought out by Mr. Stirling, of the Anatomical Museum, Edinburgh. In this little instrument we have a flat piece of brass with a hole in the centre, leading into a cylindrical chamber, at the bottom of which a screw works. A piece of elder-pith is excavated, so as to hold the tissue to be cut; and when this has been well fixed in it, the pith is squeezed into the cylindrical box through the hole in the brass plate. A razor drawn along the surface of the brass plate cuts through the pith and the tissue it embraces, leaving a surface perfectly smooth and continuous with that of the plate. A turn of the screw, which works into the cylindrical box, now causes a certain very small thickness of the pith and tissue to project above the plate, and the razor again drawn across and pressed on to the surface of the brass plate, cuts a fine section, the exact thickness of which may be nicely regulated by the screw which pushes up the pith. This little instrument may be obtained at a small cost from M. Verick, 2, Rue de la Parcheminnerie, Rue St. Jacques, Paris. It is not unlike an instrument described in English books on the microscope for cutting sections of wood, but its application with the use of pith, previously much in use for making sandwiches with delicate tissues which had to be cut, increases its value greatly. As to knives to be used in making sections, though some large knives are made on purpose, there is nothing better than a first-rate broad-bladed razor. Dr. Meynert has cut his immense collection of brain preparations with a common razor.

Staining and Mounting Tissues.—The method which is now very extensively used in German histological laboratories for the study and preservation of all kinds of delicate tissues, such as sections of the developing hen's egg, morbid growths, fine injections, nerve tissues, &c., is as follows: The section, either from a fresh specimen or from one preserved in alcohol, is placed in a solution of carmine in ammonia, from which all excess of ammonia has been allowed to evaporate, as tested by the smell. The solution is also carefully filtered before use, and diluted to a small extent. After from three to ten minutes or more in the carmine solution, the section is placed in distilled water and thoroughly washed for some time by blowing into the water with a small pipette. From this the section is removed momentarily to a watchglass containing distilled water and two drops of acetic acid, and then is placed in absolute alcohol. The water is thus removed, and in five or ten minutes the section may be placed in oil of cloves, which renders it very transparent. From this it is removed to the glass slip, and is mounted in a solution of gum damara in turpentine, such as is sold by artist's colourmen. At any stage in this process we can proceed back again by the same steps, ammonia being used in place of acetic acid, and re-stain, re-wash, or re-acidify as the case may be. If the staining is carefully managed and the subsequent washing a thorough one, most cellular structures are very beautifully and clearly brought out. Where rapidity is desired, and for the purpose of inspecting a specimen, it may be simply mounted in glycerine after the staining. The process above described is that of Gerlach and Stieda, and is preferred to any other by some observers of great experience. Thus Dr. Meynert, of the lunatic asylum at Vienna, who is throughout Germany regarded as the great authority on the histology of the brain, uses this method for mounting his sections of cerebrum, cerebellum, &c. It is very convenient to have little glass dishes with covers for each of the above-mentioned re-agents, so that the sections may be passed from one to the other and left covered up, if desired, for a day or two—the waste of re-agents involved in filling watch-glasses each time they are required being also avoided. If preparations have been preserved in chromic acid, they must be very well washed before staining, and very often cannot be made to stain well at all. Various methods are useful in various cases, but, as one of great general use, the carmine staining and oil of cloves clearing may be strongly recommended. Staining tissues with nitrate of silver, chloride of gold, and with bile-pigment are most important aids to the histologist, the merits of which have been recently much discussed, and of which we shall have a word to say from experience.

Glycerine Jelly.—This composition, which has been lately introduced, melts at a lower temperature than Deane's medium, and has a greater clearing action on the objects mounted in it. A small piece of the jelly put on a glass slip and warmed, soon liquefies, and is ready to receive any object, after which the cover is directly applied. For objects which do not require any great amount of "clearing," it is a most useful medium. Insects, worms, small crustacea, &c., may be mounted in this way excellently. E. RAY LANKESTER

METEOROLOGY OF JUNE 1870

I BEG to send you a few particulars of the weather of the past month (which was characterised by unusual atmospheric phenomena), deduced from daily observations with standard instruments, the place of observation being in latitude 51° 27′ N., longitude 0° 18′ W., height above sea level 64 feet.

The barometrical readings have been corrected for capillarity, index error determined by comparison at the Royal Observatory, Greenwich, and certified by James Glaisher, Esq., F.R.S., and reduced to 32° Fahr. and mean sea level.

The thermometrical readings have been corrected for index error determined by comparison at the Kew Observatory of the British Association.

Time of observation, thermometer $7^h\ 45^m$ A.M., barometer $8^h\ 0^m$ A.M., wind direction $8^h\ 30^m$ A.M., daily (approximate).

The following are the calculated monthly means, &c.

Mean height of the barometer (corrected)	30·135 in.
Highest observed reading	30·551 in.
Lowest observed reading	29·747 in.
Monthly range	0·804 in.
Mean temp. air ($7^h\ 45^m$ A.M.)	60·8°
,, ,, of evaporation	55·3°
,, ,, of dew point	50·6°
Relative humidity (dry air = 0, saturation = 100)	70
Mean of the maxima	75·1°
Mean of the minima	51·2°
Mean diurnal range of temperature	23·9°
Extremes: Highest reading (June 22)	91·4°
Extremes: Lowest reading (June 6)	41·6°
Monthly range of temperature	49·8°
Mean estimated force of wind (0 to 6)	1·5
Total rainfall	0·597 in.
Days on which rain fell	5
Evaporation on 22 days	3·652 in.
Mean intensity of ozone (24h)	2·5

*** Sun at greatest meridional altitude (year) or greatest N.D. June 21st.

A lunar halo (or portion of a circle) was observed on June 9 shortly after 10^h P.M. (or 10^h astronomical time). Its estimated extent was 270° of a circle whose diameter was 60°. Estimated altitude of the moon at time of observation, 35°.

A thunderstorm occurred on the 16th, with very vivid lightning, yielding 0·355 inch of rain, which was equivalent to 7987·5 gallons, 1288·65 cubic feet, or 35·9 tons per acre, assuming the rainfall to be equally distributed, which may be done with some degree of truth, as the amount measured at the Kew Observatory, one mile distant, agrees with mine to the second decimal.

The atmosphere was moderately charged with moisture during the month, which must have been an assistance to vegetation in spite of the excessive drought.

The rainfall during this month was 0·558 inch less than that registered during the corresponding period last year.

Wind directions in the lower regions of the atmosphere were observed on 12 out of 16 points, the prevailing directions being between W. and S.W. points.

Richmond, Surrey, July 7 JOHN J. HALL

THE ROTUNDITY OF THE EARTH

"PARALLAX" is not dead yet. His backer, Mr. John Hampden, has again brought his sophisms and his misstatements before the public in the form of a periodical called the *Armourer*, which has already had one period of existence, having been discontinued about four years since, "amidst the regrets of hundreds of its readers," as the editor asserts. When Mr. Hampden speaks of the recent experiment by which the falsity of "Parallax's" views was exposed, as "the Bedford Canal swindle," of Mr. Wallace's victory as having been obtained by "Scotch knavery and cunning," and of the conduct of the editor of the *Field* as umpire as having been "false, unfair, and fraudulent," we may well leave these charges to be replied to by these gentlemen themselves, or by the law. As, however, "Parallax" repeats unblushingly his assertion that he has for years propounded his views by lectures in various parts of the country without their having been once refuted, we may call to his remembrance a circumstance which he has probably found it convenient to forget. During the recent experiments at the Bedford Level, "Parallax" carefully concealed the fact that the very same test had been previously applied. In the year 1856, however, after a lecture by "Parallax," at Norwich, two gentlemen challenged him to an experimental proof of his views. He accepted the challenge and was invited to witness the experiment, which invitation, however, he did not respond to, but prudently left the town in the interim. The nature and result of the experiment are detailed in a printed slip which was inserted at the time in the local papers, and a copy of which we append:—

COPY OF AGREEMENT.—We, the undersigned, "Parallax," of No. 61, Upper North Place, Gray's Inn Road, London, on the one side, and John Weir, of No. 14, Suffolk Street, Union Place, Norwich, and Charles William Millard, of Prince's Street, Norwich, on the other side, having different opinions as to whether the Earth be a Plane or a Globe, agree to test the accuracy of our respective opinions in the following manner, that is to say, to place four flags in a straight line, intersecting the River Yare between Strumpshaw or Bradestone and Norton, for a space of not less than four miles, or six miles if possible. The flags to be at the same height above the water except the last or fourth flag, which is to be placed close behind the third flag, at a height of three feet above it; if we can see the fourth or furthest flag above the tops of the other three flags, the Earth is a plane, or if the second flag from the telescope be above a line joining the tops of the first and third flags, the Earth is a globe.—(*Signed*)—"PARALLAX;"—JOHN WEIR, C. W. MILLARD, Engineers and Surveyors.

Dated November 24, 1856 *Witness*—R. F. HINDE

COPY OF CERTIFICATE.—We, the undersigned, hereby certify and declare, that on the eleventh day of December, one thousand eight hundred and fifty-six, we accompanied Messrs. Weir and Millard, and assisted in placing the flags in the manner above mentioned, and that upon looking at the flags with a powerful telescope, the top of the second flag was fifteen inches and one half of an inch above a line joining the tops of the first and fourth flags, and twenty-four inches and one quarter of an inch above a line joining the tops of the first and third flags, thereby proving that the earth is a globe, and that from the results of this experiment, "Parallax" is bound, by the before-mentioned agreement, to renounce, for ever, his theory of the earth being a plane.—(*Signed*)—R. F. HINDE, Sussex-street, Norwich, manufacturer; ALEX. SANDERSON, Magdalen-street, Fye-bridge, tobacconist; W. H. DAKIN, Davey-place, Norwich; JAMES NEWBEGIN, St. Andrew's, tobacco manufacturer.

Will nothing stop "Parallax's" mouth?

TEA

THE word "Tea" is applied to the leaves of numerous plants from which infusions are made in their several native countries. Thus in Paraguay they use a species of Holly, in Abyssinia and Arabia the leaves of *Catha edulis*, and in Labrador those of *Ledum latifolium*.

We propose, however, in this paper, to say a few words about that article which is generally and popularly known as tea, and which forms such an important commercial commodity between China, India, and our own country, How long tea had been used in China before its introduction into Europe early in the seventeenth century no one can venture to say, but it appears to have been first known in England about the year 1660, and no article of commerce, perhaps, presents a parallel history of such rapid development. In 1678 the East India Company imported into England 4,713lb. Tea, however, continued to be a rarity for many years after that date, fetching a high price, and consequently remaining beyond the reach of all but the more wealthy. The demand for it increased so rapidly that in 1725 the consumption in the United Kingdom reached 370,323lb. Since then tea has been more and more in demand, until we find the returns for last year show as much as 139,223,298lb. imported, and 111,889,113lb. entered for home consumption, the computed real value of the tea imported during eleven months of 1869 being 9,115,823*l*.

The plant from which this large source of wealth is obtained is a shrub, the native country of which is still not definitely known. Although it has been cultivated for many hundreds of years in China, and its use alluded to in ancient Chinese legends, it has not been discovered in that country in a wild state, but truly native tea occurs in the jungles of North-eastern India.

At one time botanists were inclined to the opinion that black and green teas were furnished by two distinct species, the former by *Thea bohea* and the latter by *T. viridis*. So little difference exists between them that there seems no doubt as to their being mere varieties, and both are now usually referred to one species, the *Thea chinensis* of Linnæus. Though tea is now largely grown in Assam and some also in Japan, the plants cultivated in both countries are varieties introduced from China. The black and green teas of commerce may be prepared from either form of the plant according to the pleasure of the tea farmer, the colour in a great measure depending upon the rapidity of the artificial drying of the leaf, and also upon the length of time the freshly gathered leaves are exposed to the air before heating. There are, however, districts in China called respectively the Black and Green tea districts, in which the plants are grown specially for each purpose. For the preparation of either sort the leaves are gathered by hand, and the younger ones should alone be taken. If they are intended for the manufacture of black tea they are exposed to the air for a short time, after which they are placed in iron pans and submitted to a gentle heat for a few minutes. By this process much moisture is thrown off, and the leaves are rendered pliable, so that they are easily pressed or rolled between the hands, by which the characteristic twist or curl is given to them. Before, however, they are fit for market, they are exposed to the air for two or three days, and finally dried in iron pans over a slow fire. The chief difference in the preparation of genuine green tea is, that it has to be more quickly dried after undergoing the curling or twisting process in the hands, black tea being allowed to remain in heaps in a flaccid state, before the final drying or roasting, which, in itself, is much slower. A great deal, however, of the green tea consumed in this country, is artificially coloured by the Chinese, chiefly with Prussian blue, gypsum, and turmeric. Of course it is only inferior teas that are so treated, a good face being thus given to them. They can mostly be detected by placing a handful of the tea on a sheet of white paper; a thick, greenish dust will not only be left on the paper, but will rise every time the tea is shaken. By breaking a few leaves also with the finger nails this coloured tea will show a brownish fracture, while genuine uncoloured tea is more or less green throughout, and consequently little or no dust is deposited from it. As the leaves of true tea vary very much in size and form, adulteration with the leaves of some other plants is not so easily detected. The nearest approach, however, to the form of the true tea leaves are those of *Camellia sasangua*. This plant itself is a near botanical ally to the tea, and the leaves are moreover used by the Chinese for scenting many of their teas. Most other leaves which have been found as adulterants may be detected by their forms.

We give a figure of a leaf of true tea.

If a leaf of black tea be soaked in cold water, spread out, and inspected through a microscope of ordinary power, it will present the appearance shown in the cut, the older and larger leaves will be of a dullish green, and the younger ones of a light semi-transparent green. It will not serve us to examine the internal structure of the leaf, as it has many points in common with other leaves, and would moreover require minute examination. The best black tea, then, should present the appearances above indicated, and the same may be said of green tea, with this exception, that after being soaked it is of a paler green colour than the former.

Amongst the commercial varieties of tea the following are the best known:—Congou: this constitutes the bulk of black tea from China. It is that which is usually sold as black tea, and of course varies much in price according to its purity; a really good tea of this description ought to be had at the present time at 2*s*. 6*d*. per lb.

Souchong and Pekoe are both finer kinds of black, and fetch higher prices. Another kind of black called Orange Pekoe, may be known by its long, wiry leaves, which are mostly genuine; it is artificially scented, and is generally used by grocers for mixing with inferior kinds. A fine Pekoe, however, ought to be obtained for about 4*s*. per lb.

Caper is a common black tea, artificially scented; the leaf as we see it in commerce has the form of the Gunpowder leaf, but these are made up of tea-dust and other matters agglutinated.

Amongst green teas, genuine Gunpowder is the finest; the qualities and prices however vary very much; the leaves of the best are in fine, close curls, and are the younger ones gathered from the tops of the plants. The lower qualities of this tea are almost all coloured artificially, and many contain no perfect or whole leaf at all, but are made up of broken tea-leaves; 4*s.* 6*d.* per lb. may be considered a fair price for a good quality Gunpowder tea. In Hyson the leaf is longer than Gunpowder; it is mostly composed of the true leaf, but is very frequently artificially coloured.

Oolong is really a green tea, but with so black an appearance that its colour is only developed by putting it in hot water. It is artificially scented, and is used for mixing with other kinds of tea.

The cultivation of tea in Assam has sent several good kinds into our markets, the Congou, Souchong, and Flowery Pekoe of these plantations being, as hitherto imported, all genuine teas. We regret, however, to see that in the course of the past few weeks a quantity of artificially coloured green tea has been imported from the Indian plantations. Many of the Assam teas have a fine malty flavour, which is so much esteemed that it is frequently imitated and imparted to other teas in London.

A great deal that has been said and written for many years past on the subject of adulteration of food we are bound to admit as truth, but, on the other hand, there has

FIG. 1.—Tea (*Thea chinensis*, L.)

been some exaggeration. With regard to tea, the great demand amongst all classes has led to a very keen competition, not only amongst retail dealers, but also amongst importers themselves. The system of mixing inferior articles with those of better quality must not be wholly laid to the charge of the British tradesman or merchant, for the natives of the several countries producing the various commercial products, practise a great amount of deception. The importation of several chests of such rubbish as the "fine Moning Congou," about which so much talk was made a few weeks since, as well as the numerous cargoes of "tea-dust," a sample of which is now before us, composed of small fragments of various kinds of vegetable matter and other substances, with little or no tea, are proofs that others than the retail dealers are the most culpable. We are ashamed to own that in many instances this system of deception has been taught the natives by our own countrymen; but such is not always the case, and other articles besides tea, as we shall have occasion to show in the course of these papers, are equally subject to native adulteration. A system of manufacture of spurious tea, called "Lie Tea," is openly known to exist in China, and was at one time profitably carried on in England. It consisted in converting the leaves of numerous plants into imitation tea for the purposes of adulteration. Though teas of varied qualities are imported from China, those of the very finest kinds seldom leave the country, except a small quantity which is carried overland to Russia, where they sell for as much as 50*s.* per lb., and the same price is even paid by the princes and mandarins of China in the very country where the tea is produced. It is said that these fine teas would deteriorate in quality in such a journey as that from China to England. A fine variety of Assam tea called Flowery Pekoe, is now chiefly imported for the Russian trade, very little of it being sold in this country. It is worth about 7*s.* 6*d.* per lb., consequently there is little demand for it. Though the Russians boast, and with good reason, of the quality of their tea, a vast quantity of rubbish is sent to that country from China for consumption by the poorer classes. This is known as Brick Tea, and is frequently made up of the sweepings of the manufactories and warehouses mixed with bullock's blood and other refuse, and compressed into hard cakes or bricks; for use it has to be boiled. In some parts of India the natives use a similar kind of brick tea, making, instead of a clear infusion, a thick kind of drink more like soup.

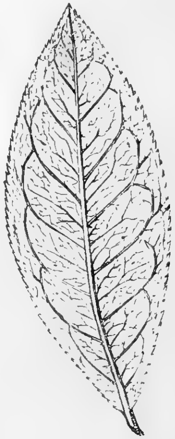

FIG. 2.—Leaf of the Tea Plant—natural size of a full-grown leaf.

Tea contains an active principle called "theine" and a volatile oil, it also contains about fifteen per cent. of gluten or nutritive matter, and about twenty-five per cent. of tannin or astringent matter. The effect of theine upon the human system is to excite the brain to greater activity, but whether or not it soothes the vascular system by preventing the rapid waste of the body, is a point upon which physiologists are not quite agreed. Theine, however, if taken in excessive quantities produces tremblings, irritability, and wandering thoughts, it has been recommended that when these symptoms show themselves, cocoa should be used as a beverage for a few days. The volatile oil is narcotic and intoxicating; it is to this oil that the flavour and odour of tea are due, it is of course present in larger quantities in new teas than in old, therefore the fresher the teas are the fuller is their flavour and odour, consequently no kind of tea improves by being kept exposed to the air or even in paper, so that tea weighed at the time of purchase should be preferred to that sold in packets, the buyers of such tea having to risk the length of time it has been packed; and, moreover, the teas themselves are usually of an inferior description.

Since writing the above, I have had two samples of green tea sent me which have been offered for sale in London during the past week. One sample is composed of nearly or quite half its weight of the young fruits of the tea-plant about the size of small peas, the remainder being made up of broken tea-leaves agglutinated and rolled together, and enclosing fragments of various matters, mineral as well as vegetable, which, of course, are included for the purpose of increasing its weight and bulk. The other sample consists principally of leaf stalks, a few leaves, rice husks, and the pappus fruits of some Compositæ. Truth compels me to say that all the leaves I have examined out of these samples have been leaves of the true tea-plant, or rather fragments of such, but all artificially coloured, and so superficial is the colouring that it can be easily wiped off with the dry finger. These teas have been offered for sale, one at $1\frac{1}{4}$*d.* and the other at $1\frac{1}{2}$*d.* per lb., the duty paid on them being equal to that charged on the best teas—namely, 6*d.* per lb.

This class of tea can, of course, only find a sale amongst unscrupulous tradesmen, who buy it to mix with good teas, and where a comparatively small proportion of this rubbish is mixed with a large quantity of good tea, but yet in sufficient bulk to increase the tradesman's profits, it is difficult for the purchaser to detect a few hundred or more such leaves in the thousands which go to form a pound of tea. It is high time there was some regular system of examination of such articles directly they come into port.

J. R. JACKSON

NOTES

PROFESSOR HELMHOLTZ has left Heidelberg for Berlin, to occupy the position left vacant by the death of Magnus, but with the title of Professor of Physiology.

AT the meeting of the French Academy on the 4th inst., Professor Brandt was elected a correspondent of the section of Anatomy and Zoology. In the final election he received twenty-two votes out of thirty-eight, the remaining sixteen being in favour of Mr. Darwin. In the first ballot Professor Huxley received three votes, and M. Loven one.

ONE of the improvements in the management of the Hunterian Museum of the Royal College of Surgeons, introduced by the present Conservator, has been the publication of an annual report of the progress and condition of the collection, and the exhibition in the theatre of the College, of the specimens that have been added to the Museum during each twelvemonth. As the College year ends at Midsummer, this exhibition has just taken place, and has enabled those interested in the Museum to judge of the nature and value of the additions, and the mode in which they have been prepared. The new specimens include fifty-five specimens of pathological anatomy, one hundred and eleven of normal human and comparative anatomy; the latter chiefly prepared from animals which have died in the Zoological Society's Garden, and a considerable series of skeletons and skulls. We propose to refer more fully to Professor Flower's Report on a future occasion.

THE naturalists of Switzerland have decided to form a scientific congress devoted to the study of the natural phenomena of the Swiss Alps, to include the geologists and palæontologists of France, Germany, and Italy, who have paid special attention to this subject, to be held in Geneva on the 31st of August and 1st and 2nd of September, and to be called the Congress of Alpine Geologists. Among the promoters of the congress are Prof. Studer, of Berne; Prof. Mérian, of Bâle; Prof. Escher de la Linth, of Zürich; Prof. Desor, of Neuchâtel; Prof. Favre, of Geneva; Profs. de Loriol, Heer, and Mousson, of Zürich; Prof. Rütimeyer, of Bâle; Prof. Renevier, of Lausanne; Profs. Vogt and Pictet, of Geneva. A committee for the organisation of the congress has been formed at Geneva, with M. Pictet as president, M. Alphonse Favre as vice-president, and MM. Ernest Favre and E. Sarazin as secretaries. All geologists interested in the subject are invited to be at the president's reception on the evening of August 30th, and anyone wishing to communicate any address or paper is requested to write to M. Ernest Favre, 6, Rue des Granges, Geneva.

WE are pleased to hear that the Government of Demerara has re-considered its resolution for discontinuing the geological survey of that colony, and has now resolved to complete it, under the direction of Mr. Charles B. Brown, an associate of the Royal School of Mines.

A SPECIAL extra meeting of the Syro-Egyptian Society of London will be held on Tuesday, July 19, at half-past seven P.M., for the exhibition of a collection of drawings of Egyptian antiquities, by the late R. Hay, F. Arundale, and C. Laver, Esqs. Messrs. Simpson and Bonomi will give explanations.

AT a meeting of the trustees of Owens College, Manchester, held on Thursday, the 7th inst., the vacancy caused by the resignation by Professor W. Jack, M.A. of the Natural Philosophy Professorship, was filled up by the appointment of Dr. Balfour Stewart, F.R.S., superintendent of the Kew Observatory, to the Senior Professorship, and of Mr. James Thomson Bottomley, M.A., F.C.S., Demonstrator and Lecturer in Natural Philosophy in King's College, London, to the Junior Professorship of Natural Philosophy. Dr. Stewart was also appointed Director of the Physical Laboratory which is about to be established in the college. We are informed that Mr. Bottomley has since withdrawn.

M. CLAUDE BERNARD has been elected a member of the Imperial Council of Public Instruction in France for the year 1869-70; M. Briot has been appointed Professor of Mathematical Physics and the calculus of probabilities in the Faculty of Sciences at Paris; and M. Emery, Professor of Geology, Mineralogy, and Botany in the Faculty of Sciences at Dijon.

THE annual public meeting of the Paris Academy of Sciences for the distribution of prizes and rewards, which should have been held in December last, was postponed till the present month, and is now again put off for some unexplained cause.

IT is with great pleasure we hear that the London Institution, in Finsbury Circus, has appointed Mr. John Cargill Brough to the post of Librarian. The library of this Institution is so valuable that it is fitting it should be under the care of a man who combines literary and scientific qualifications in so eminent a degree. It was right that an office once filled by such men as Maltby and Brayley, should have fallen into good hands.

WE understand that Dr. B. H. Paul has been appointed editor of the *Pharmaceutical Journal*, the new series of which we recently announced.

THE list of members of the Institution of Civil Engineers, corrected to July 1, 1870, contains the names and addresses of 16 honorary members, 702 members, 999 associates, and 177 students, making together 1,894 of all classes.

THE House of Commons decided on Friday last that the land belonging to the Thames Embankment shall be kept entirely free from building. The Natural History Museum will therefore occupy the ground already indicated by us on the space adjoining the Royal Horticultural Gardens.

Apropos of this subject, one of our daily contemporaries (and by no means the worst informed on scientific subjects) makes ludicrous blundering. While generously affirming that "any back street will do for a museum," it maintains that "Englishmen cannot fairly be charged with undervaluing Natural History; witness the crowds that throng the great Grecian temple in Bloomsbury, to pause at the cases of stuffed monkeys, and to marvel at the *horns of the megatherium!!*" as indeed well they may. Whether Englishmen can be charged with undervaluing natural history or not, it is clear that newspaper leader writers can be charged with expressing a confident opinion on subjects in which they are unacquainted with the most elementary facts. Clearly there is room for more science teaching.

AT a recent meeting of the Franklin Institute of Philadelphia Professor Morton resigned the office of Resident Secretary, he having received an appointment in a distant city. The resignation was accepted, and the President stated that Professor Morton had consented to continue his charge of the *Journal of the Franklin Institute*, which had achieved so desirable a position under his management. The new position accepted by Professor Morton is that of President of a College of Mechanical Engineering, to be established in Hoboken, opposite New York. He is succeeded at the Institute by Dr. W. H. Wahl.

THE Council of the Institution of Civil Engineers has awarded the following premiums:—1. A Telford Medal and a Telford Premium, in books, to Edward Dobson, Assoc. Inst. C.E., for his Paper on "The Public Works of the Province of Canterbury, New Zealand." 2. A Watt Medal and a Telford Premium, in books, to R. Price Williams, M. Inst. C.E., for his Paper on "The Maintenance and Renewal of Railway Rolling Stock." 3. A Watt Medal and a Telford Premium, in books, to John Thornhill Harrison, M. Inst. C.E., for his Paper on "The Statistics of Railway Income and Expenditure, and their bearing on future Railway Policy and Management." 4. A Telford Medal and a Telford Premium, in books, to John Sopwith, jun., M. Inst. C.E., for his Paper on "The Dressing of Lead Ores." 5. A Telford Medal and a Telford Premium, in books, to James Nicholas Douglass, M. Inst. C.E., for his Paper on "The Wolf Rock Lighthouse." 6. A Watt Medal and a Telford Premium, in books, to George Berkley, M. Inst. C.E., for his "Observations on the Strength of Iron and Steel, and on the Design of parts of Structures which consist of those Materials." 7. A Watt Medal and a Telford Premium, in books (to consist of the second series of the Minutes of Proceedings, vols. xxi. to xxx. inclusive), to Robert Briggs, of Philadelphia, U.S., for his Paper "On the Conditions and the Limits which govern the proportions of Rotary Fans." 8. A Watt Medal and a Telford Premium, in books, to Edward Alfred Cowper, M. Inst. C.E., for his Paper on "Recent Improvements in Regenerative Hot Blast Stoves for Blast Furnaces." 9. A Telford Premium, in books, to John Grantham, M. Inst. C.E., for his Paper "On Ocean Steam Navigation, with a view to its further development." 10. A Telford Premium, in books, to Daniel Makinson Fox, M. Inst. C.E., for his "Description of the Line and Works of the Sao Paulo Railway, in the Empire of Brazil." 11. The Manby Premium, in books, to Emerson Bainbridge, Stud. Inst. C.E., for his Paper on "Coal Mining in Deep Workings." The Council have likewise awarded the following prizes to students of the Institution:—1. A Miller Prize to Robert William Peregrine Birch, Stud. Inst. C.E., for his Paper on "The Disposal of Sewage." 2. A Miller Prize to Henry Thomas Munday, Stud. Inst. C.E., for his Paper on "The Present and the Future of Civil Engineering." 3. A Miller Prize to William Walton Williams, jun., Stud. Inst. C.E., for his Paper on "Roads and Steam Rollers." 4. A Miller Prize to Sidney Preston, Stud. Inst. C.E., for his Paper on "The Manufacture and the Uses of Portland Cement." 5. A Miller Prize to Edward Bazalgette, Stud. Inst. C.E., for his Paper "On Underpinning and making good the Foundations of the Irongate Steam Wharf, St. Katherine's, London." 6. A Miller Prize to Josiah Harding, Stud. Inst. C.E., for his Paper on "The Widening of the Liverpool and Manchester Railway between Liverpool and Huyton, and on the Construction of a Branch Line to St. Helen's." 7. A Miller Prize to the Hon. Philip James Stanhope, Stud. Inst. C.E., for his Paper on "The Metropolitan District Railway."

THE fabled alligator captured in the Thames some months ago has been surpassed by a hippopotamus disporting itself in the Seine. The scarcity of water has been so great in the Jardin des Plantes, that his majesty had been taken by his keepers to the river for his daily bath, securely held, as was thought, by his chain. One day, however, he snapped his chain during his gambols, to the no small dismay of the *blanchisseuses* and steamboat passengers, one lot of whom he threatened to demolish at a mouthful. Several keepers who attempted to board him were treated to a playful ducking, but after the upsetting of a good number of small boats, he was at length captured and hauled ashore. The poor brute must have thought that the good old times of the pre-glacial epoch had returned.

A SPECIAL general meeting of the Fellows of the Royal Geographical Society was held on Monday last at the Royal Institution, Albemarle-street, to consider the question of purchasing a large freehold house for the society's map rooms, library, and offices. The president, Sir Roderick Murchison, explained the necessity for further accommodation, and stated that the Council had at length concluded to purchase the large house No. 1, Savile Row. The meetings, however, would still be held in the great hall of the University of London. The resolution to purchase the property in Savile-row for 14,400*l.* was carried without opposition.

THE Second Report of the King's School Natural History and Natural Science Society, Sherborne, shows the activity with which the study of natural science is followed in the school. As might be expected in so rich a neighbourhood, geology appears to be the branch of science most zealously cultivated.

WE have received the First Annual Report of the American Museum of Natural History. Until 1869 New York was behind Boston, Philadelphia, Washington, and Chicago in possessing no Natural History Museum, a position which a number of gentlemen then determined their city should no longer occupy. Rooms were therefore secured in a building in the Central Park, and large subscriptions were at once collected, and employed in purchasing collections in Europe. Baron Osten-Sacken and other gentlemen also made large donations of specimens and books; and thus, without any assistance from the State except a grant from the duplicate specimens of Natural History belonging to it, the New York Museum of Natural History is in a fair way to become one of the most important on the continent.

THE Natural History Association of Natal has issued its second report. Papers were read during the past session by the Rev. Dr. Callaway, on phenomena occurring among the natives akin to mesmerism, the basis of their faith in divination, in which many interesting and striking facts were brought forward. Mr. Windham's paper on "The Gamebirds of Natal," was illustrated by a collection of mounted specimens, chiefly shot by himself, and generally identified by Mr. Layard, whose work on the birds of South Africa forms the recognised authority on the subject. In entomology, valuable papers were read by Mr. H. C. Harford, on the larvæ and pupæ of some Lepidoptera of Natal; by Mr. Morant, Notes of a collecting trip in the Transvaal, during which several new and interesting species were captured; and by Dr. Seaman, on protective resemblances in some local forms of insect life. In botany there are records of a new climbing Scrophulariaceous plant, *Buttonia natalensis*, discovered by Mr. E. Button, and of a new date-palm, detected by Mr. M'Ken, curator of the Natal Botanic Gardens. The colony may be congratulated on possessing so energetic a society.

THE Portuguese Consul-General at Bangkok, a hale man and an excellent swimmer, while bathing in the River Menam, suddenly sank from having come into collision with an electric eel, and was drowned. The Siamese say such deaths are not uncommon.

WE have received from Mr. M. J. Barrington-Ward a syllabus of a course of botanical lectures recently delivered at Clifton College, accompanied by the following gratifying remarks :—"My lectures were attended, I should say, by 100 ladies, and I can well bear out what was said in NATURE a few weeks ago as to the ability which women display at such classes. I never met with so much diligence and real skill in pupils before, and I only wish I could send you some of the papers written by these ladies to show how well and logically they handled a scientific subject."

MR. W. CROOKES has reprinted for private circulation his article in the current number of the *Quarterly Journal of Science* on "Spiritualism viewed by the Light of Modern Science." While admitting that phenomena have come under his notice which seem inexplicable on any known physical laws, the main part of Mr. Crookes's paper is occupied by a statement of the tests to which "Spiritualists" should subject their manifestations, which they have at present failed to do.

"DER rationelle Wiesenbau, dessen Theorie und Praxis," by L. Vincent, an exhaustive treatise on arable agriculture, has now reached its third enlarged edition.

*FACTS AND REASONINGS CONCERNING THE HETEROGENOUS EVOLUTION OF LIVING THINGS**

III.

THE results at which we have arrived now require to be looked at from two or three different points of view.

In the first place, with regard to these latter experiments, in which, with the help of Dr. Frankland, a perfect vacuum was procured in the experimental flasks previous to their being hermetically sealed, and before the exposure of them and their contained fluids to the temperature of 146 to 153°C. for four hours, it is desirable to know what the influence of such a temperature would be upon fungus-spores and filaments purposely exposed thereto. It is certain that, so far as all experimental observations have gone at present, no fungus-spore has been known to germinate after it has been exposed in a fluid to a temperature of 100°C. for even a few seconds.† What then would be the effect of a temperature of 150°C. for four hours? Is it possible that a fungus-spore or a fungus-filament at all similar to those which were met with in the preceding experiments could remain as such—could retain its morphological characters, in fact, after an exposure in fluid to a temperature of 150°C. for four hours? With the view of answering this question, I placed a quantity of a small fungus, consisting of mycelial filaments and multitudes of spores, closely resembling although not quite so delicate as those which were met with in the saline mixtures, into a solution (of the same strength as that which had been previously employed) of tartrate of ammonia and phosphate of soda in distilled water, and then handed it over to Dr. Frankland with the request that he would kindly treat this in the same way as he had done the other four solutions. Accordingly, on May 11, a vacuum having been produced within the flask before it was hermetically sealed, the solution was submitted in the same digester to a temperature of 146° to 153°C. for four hours When taken out from the digester, the previously whitish mass of fungoid filaments and spores had assumed a decidedly brownish colour, and it was in great part converted into mere *débris*. On the following morning the flask was broken, and some of the remains of the fungus and its spores were examined microscopically. *The plant was completely disorganised: not a single entire spore could be found;* they were all broken up into small more or less irregular particles, and the filaments were more or less empty, containing no definite contents, and being only represented by torn tubular fragments of various sizes. This utter disorganisation was in striking contrast with other specimens of the fungus, as it existed before exposure in the digester, which I had mounted in order to retain for purposes of comparison. And from the amount of destructive influence which was exercised upon the microscopic fungus in question, we may fairly imagine that the destructive influence of a similar temperature for four hours upon the still more delicate fungus represented in Fig. 17 would have been by no means less in extent. It would seem, at all events, well-nigh impossible that such a fungus could have pre-existed in the solution before its exposure in the digester, and could afterwards have retained all its morphological characters unimpaired, as they may be seen in the specimen now in my possession, from which the above-mentioned drawing was made. The plant must have been developed, therefore, within the flask itself subsequently to its exposure in the digester. What then could its origin have been? No fungus-spore has hitherto been known to germinate—no previously Living thing has been known to live—after the fluid containing it has been raised to a temperature of 100° C. for a few seconds. The fluid in Experiment 19 had however been raised to a temperature of 146° to 153° C. for four hours. We have even seen, in addition, that such a temperature completely disorganises certain closely allied fungus-spores, so that there is good reason for presuming that it would be similarly destructive to such spores as are represented in Fig. 17 if they had pre-existed in the solution. All that I have just said applies equally to the fungus-spores found in Experiments 18 and 20, and to the Ciliated Monad found in the turnip solution.

For the present, therefore, all presumptions, based upon the best available scientific evidence, are strongly in favour of the *de novo* evolution of these organisms within their respective flasks.

Whilst it seems, however, that the Living things which were found in these four experiments must have been evolved *de novo*, it does not follow necessarily that they were evolved in Experiments 19 and 20 out of the re-arranged elements of the saline substances themselves, because no proof has been offered that these substances were chemically pure. That such *may* have been the origin of these Living things seems, however, to be possible from what I have already said, and will, I think, appear even probable, after a due consideration of some of the facts which are now about to be related.

"Germs" are supposed by many to be universally diffused, more especially in the air and within organic substances. It seemed possible, however, and only reasonable, to suppose that they might exist much less abundantly in saline materials than within organic substances, and this was one reason why such materials were made use of in my later experiments. In order to ascertain whether any visible organisms or spores were to be found in the saline materials employed, portions of these have been repeatedly dissolved by distilled water in a watch-glass, and the fluid has afterwards been submitted to the most careful microscopical examination. Moreover, after sufficient time has been allowed for subsidence, the bottom of the watch-glass has then been most carefully scrutinised by a powerful immersion lens. The saline materials employed in the preceding experiments have been potash-and-ammonia-alum, tartar emetic, phosphate of soda, phosphate of ammonia, oxalate of ammonia, acetate of ammonia, carbonate of ammonia, and tartrate of ammonia. The result of repeated examinations of these substances in the manner above stated, has been that not a trace of anything like an organism—no fungus-spore, germ, or egg of any kind—has been found in solutions of any of the substances employed, except in one. This one in which such bodies have been found is that which I have named last—the neutral tartrate of ammonia.

Several of these salts—the oxalate, the acetate, the carbonate, and the tartrate of ammonia—contain within themselves all the ele-

* (Concluded from p. 201.)

† Such a temperature, also, very frequently suffices to produce a considerable amount of disintegration in fungus filaments which are submitted to its influence. It is almost impossible that a perfect organism with a mass of loose spores around it could have braved such a temperature for fifteen minutes, and could then have presented an appearance such as is represented in Fig. 14, the original of which is still in my possession. If not the result of a new evolution, therefore, this fungus must have been developed from a spore which was able to germinate after having been boiled for fifteen minutes; and if so it would be an exception to a rule which has hitherto been found to be general.

ments necessary for the building up of organic substances. Nitrogen, carbon, hydrogen, and oxygen are there, and only require to fall into other modes of collocation in order to give birth to an organisable material. The crystals of the oxalate are very small, those of the acetate are very deliquescent, and carbonate of ammonia exists generally in the form of non-crystalline cakes.* The neutral tartrate, however, exists in the form of large distinct prismatic crystals. Solutions of the first three substances showed no trace of Living things; though organisms were frequently discovered when crystals of tartrate of ammonia were examined.

Before describing these organisms more particularly, it will be well to glance for a moment at the origin or mode of preparation of this salt. The tartaric acid entering into its composition is obtained from *argol*—the crude bitartrate of potash derived from the grape. And although this latter salt is derived from the tissues of a Living plant, the processes to which it is submitted, in order to obtain the tartaric acid in an uncombined state, would most certainly destroy all living "germs" that might have been contained therein. After a solution of the bitartrate of potash has been boiled for a time, tartrate of lime is gradually precipitated by the addition of chalk and chloride of calcium. The insoluble tartrate of lime, after having been washed several times, is then brought into contact with *strong sulphuric acid, diluted with only about four times its bulk of water*, and this mixture is boiled for half an hour.† All this is necessary before a filtrate can be obtained from which the first crystals of tartaric acid are procurable. Ammonia, the other constituent of the neutral tartrate, being a product of the destructive distillation of coal tar, and itself exercising such a destructive influence upon organic matter when existing in the form of strong *liquor ammoniæ*, would not seem to be a very promising nidus for organic "germs." The neutral tartrate of ammonia is, however, prepared by mixing a solution of tartaric acid, procured as above mentioned, with an adequate quantity of liquor ammoniæ, and then evaporating the mixture at a gentle heat. Thus prepared, the crystals contain a notable quantity of water of crystallisation, and are not specially liable to contain organic impurities.

In the stock of crystals that I obtained from Messrs. Hopkin and Williams,‡ and which had been made about six months previously, some were well formed, and almost perfectly transparent, whilst others were less regular in shape, and presented an opaque appearance with more or less of striation within. When a crystal of moderate size was taken, about $\frac{1}{3}''$ in diameter, or a portion of a larger one, and was placed in a large watch-glass with some distilled water, it was frequently found that at first a certain number of opaque-white scales, having a granular aspect under a high magnifying power, dropped from the surface of the crystal to the bottom of the watch-glass. This material, which seemed to have been produced by some superficial alteration of the substance of the salt, dissolved with much more difficulty than the unaltered matter of the crystal. It remained for a long time at the bottom of the glass, and only very slowly disappeared. As the substance of the crystal slowly dissolved away, a number of large and small gaseous bubbles gradually escaped from it. When the crystal was examined with a one-inch object-glass whilst solution was taking place, these air bubbles could be seen at first within cavities, from which they were afterwards liberated by a solution of their walls. Occasionally, from the very centre of a crystal, from which bubbles of gas had been escaping, there floated out a very small and almost invisible filamentary mass, more or less thickly studded with minute air bubbles. Such masses were just visible with an ordinary pocket-lens, and when transferred on the point of a needle to a slip of glass, and examined with a magnifying power of about 600 diameters, they were found to contain more or less of the following constituents:—(1) a minute fragment of cotton or paper fibre; (2) a variable quantity of an almost transparent, insoluble plate-like substance, homogeneous, though broken up in all directions by intersecting cracks; (3) more rarely a small quantity of a tenacious mucoid matter, containing refractive protein-looking granules of various sizes; (4) a quantity of a colourless, confervoid-looking mass, some of whose smaller filaments, $\frac{1}{20000}''$ in diameter, looked like a mere linear aggregation of irregular masses of protoplasm, though in certain larger filaments continuous with these it became obvious that the irregular protoplasm masses were contained within a delicate hyaline cylinder across which dissepiments were sometimes to be seen, as in very minute fungus-filaments; (5) and lastly, certain fungus-spores in almost all respects similar to those which have been met with in so many of the saline experimental fluids. Although four or five of these were frequently interspersed amongst the confervoid-looking filaments, they did not seem to be in organic connection with them. The confervoid-looking, though really abortive fungus-filaments, were also almost precisely similar to the filaments containing irregular masses of protoplasm which were met with (in Experiments 12 and 13), in solutions containing tartrate of ammonia.

Repeated examination of crystals during their dissolution convinced me that such organic bodies invariably came from the interior of the crystal, often from its very centre, and that they were not to be met with on its surface. Seeing, however, that minute shreds of cotton or paper fibre also as frequently came from the interior of the crystal,* it was obviously possible that the organisms met with might have been engaged mechanically during the process of crystallisation, just as it must have happened with the shreds above mentioned. From what has previously been stated concerning the mode of preparation of the neutral tartrate of ammonia and the origin of its constituents, it may be considered almost certain that these organisms could not have pre-existed in the strong *liquor ammoniæ*, and that all living organisms which might by chance have been associated with the bitartrate of potash must have been hopelessly destroyed by the boiling with sulphuric acid, which occurred at one stage in the process employed for the separation of the tartaric acid from its base. During the subsequent process of crystallisation of the tartaric acid from its mother liquor, it is of course possible that any spores existing in the adjacent atmosphere might have dropped into the fluid, and have then become mechanically enclosed within the crystals; and the same chance of such a contamination with spores would exist during the process of crystallisation of the tartrate of ammonia itself. If this, however, had been the real source of the fungus-spores and masses of confervoid-looking filaments, such bodies *might* be found in freshly prepared crystals just as well as in those which had existed for six months.† I therefore asked Messrs. Hopkin and Williams to prepare for me a fresh batch of crystals of neutral tartrate of ammonia. This they were kind enough to do; obtaining them in the same place by the same process, and exposing the mother liquor in a precisely similar way.

An examination of some of these crystals, whilst they were being dissolved by distilled water in a watch-glass, showed that (unlike the older crystals) they were not at all coated on the surface by the comparatively insoluble granular plates; and that only a few very small air bubbles emerged from their interior. And at the bottom of the watch-glass, neither during dissolution nor afterwards, was there seen any trace of the confervoid-looking filaments or of the fungus-spores, though minute shreds of cotton and paper fibres were seen similar to those which were found in the older crystals. An examination of a large number of the new crystals was attended with similar results to those just mentioned.

This absence of the *confervoid-looking filaments* and of the *large fungus-spores* from the recently prepared crystals may be accounted for by either one of two suppositions:—

First. It may be supposed that in the case of the older crystals, the spores and filaments had dropped as such into the solutions in which the tartaric acid alone, or the tartrate of ammonia was crystallising; that they were mechanically engaged in the crystals, and were subsequently liberated unchanged (without having undergone any growth or development) on the dissolution of the crystal.‡ Whilst, on the other hand, in the case of the recent crystals, it may have happened that no such filaments or spores were floating in the atmosphere at the time of *their* formation, and that, consequently, none could have dropped into the solutions. Hence none of these could have been enclosed within the crystals.

* Obtained by a process of sublimation at high temperatures.

† The boiling point of such a solution would be several degrees above 100° C. Heat and acid combined exercise a most powerfully destructive influence upon organic matter, though even *very* dilute sulphuric acid, at *ordinary* temperatures, has been found to be peculiarly destructive to all Living things.

‡ Of New Cavendish Street.

* I had often been surprised at finding such shreds when I submitted some of my experimental fluids to microscopical examination, knowing that I had frequently used freshly prepared distilled water, and had taken every precaution thoroughly to cleanse the flasks which were employed.

† I have been unable to obtain crystals of the neutral tartrate of ammonia of an older date than this, and I should feel much obliged to any one who could send me such specimens, or who could furnish me with a few *crystals* of carbonate of ammonia.

‡ If they had been engaged within the crystals of tartaric acid, they must have been liberated from these during the preparation of the neutral tartrate, only to be re-entangled whilst the crystals of this salt were forming.

This supposition is, I think, unlikely to be the real explanation of the difference between the two sets of crystals. My reasons for so thinking will, however, appear more fully during the discussion of the other supposition.

Second. It may be supposed, on the other hand, that the confervoid-looking *filaments* and the *spores* are organisms which have assumed their existing forms and dimensions by a process of growth and development within the crystal, and that *the starting-point of each alike was a mere speck of Living Matter.*

By this supposition we give the panspermatists the full benefit of our microscopical researches, and so narrow their real requirements in the matter of pre-existing spores. It becomes a much simpler case for them, if instead of being compelled to calculate upon the pre-existence of fully formed fungus-spores, and of confervoid-looking filaments, they need only presume upon the pre-existence of a mere speck of Living matter less than $\frac{1}{60000}$″ in diameter. I most candidly confess, however, that the pre-existence of such specks of living matter is all that is really necessary for them.* Most of those who have worked much at the microscopic investigation of the organisms met with in organic infusions, must have come to the conclusion that there is no break in the continuity of that developmental series which commences with the mere speck of living matter—the primordial *Monad*—and thence proceeds through such forms as the *Bacterium*, the *Vibrio*, the *Leptothrix* filament, and the mycelial filament of a microscopic fungus. I do not mean to say that this is a necessary order of development, which invariably occurs—far from it, but rather that, as *Bacteria* commence their visible existence in the form of Monads, so *Vibrios* are but the developed representatives of certain *Bacteria*, just as the various kinds of *Leptothrix* filaments grow from certain pre-existing *Vibrios*, and just as certain of these *Leptothrix* filaments themselves may perchance become modified into larger segmented fungus-filaments, which, under favourable conditions, may fructify and produce spores, each of which is capable of developing into a plant like its parent in its latest phase of evolution. Originating, then, in the form of the minutest visible Living speck, we may find an organism passing more or less rapidly through the *Bacterium* and the *Vibrio* phase in order to grow into a *Leptothrix* thread, which, in its turn, by further growth and development, may give rise to a microscopic fungus producing large and definite spores. These fungus-spores, under similar influences, are capable of developing at once into a mycelium similar to that from which they have been produced. They do not again go through the lower terms of the series, but are veritable spores, serving only immediately to reproduce a fungus. It is an undoubted fact, on the other hand, which although often stated, is not generally known or admitted, that *Torula* cells and other fungus-spores may also originate as minutest visible *Living specks, which grow and develope at once into fungus-spores,* instead of passing through the intermediate stages of *Bacterium, Vibrio, Leptothrix*, and fungus-mycelium.

* Although this supposition is so far favourable to the views of the panspermatists, since it makes their real requirements so much more simple, still I am afraid they will find it a most troublesome and unorthodox supposition, unless they are disposed at the same time to become out-and-out developmentalists. Their position would be a much more easy one than it is at present if they chose to maintain that such specks of living matter—whatever their precise origin may have been—are practically mere specks of indifferent living matter, having no inherent tendencies, but plastic to the full, and capable of growing into such forms as their environing conditions may determine. (But having thus "swallowed a camel," why should they "strain at a gnat"? Why should they not also believe that the speck of indifferent living matter itself was formable by concurrence of necessary matter and conditions?) Unless the panspermatists were to adopt some such thorough-going developmental views as that which I have just indicated, they will gain comparatively little from the concessions which science compels us to make to them. They will better be able to reconcile their position with the comparative paucity of definite spores and germs which are actually detectable in the atmosphere; but they will find it as difficult as ever to account for the fact *that the right spores or germs should always be in the right place at the right time.* Very little short of a belief that each cubic inch of air contains the germs of myriads of organisms which are known, or which may hereafter be found under previously unknown sets of conditions, would be adequate to account for all the known and observable correspondences between the organisms found, and the precise nature of the fluids employed. And although the wildness and extreme improbability of this supposition must seem patent to all who have a knowledge of such subjects, strange to say, there are very many scientific men who would rather harbour such a belief—who would even, in spite of all laws of evidence, think it more probable—than another supposition, which is, on the contrary, in thorough harmony with all the main principles of their scientific creed. That a "vitalist" should reject this other supposition I can understand; but that all those scientific men—and they are happily numerous—who have discarded the notion of a special "vital principle," should still reject the notion that Living matter is capable of being evolved under suitable conditions and yet should accept this Panspermic hypothesis seeing the nature of the evidence which is respectively adducible in favour of the two views—seems to me almost inexplicable.

There is, indeed, strong reason for believing that the spores and confervoid-looking filaments in question have not dropped as such from the atmosphere, but that they are, rather, organisms which have developed within the crystal. It is almost impossible not to be struck with the improbability of the former of these alternatives, on account of the number of such large spores and filaments which this supposition would require to have been present in the atmosphere over the pans containing the crystallising materials, as compared with the extremely limited number of such large organisms which have ever been obtainable when experimental observations have been made upon the nature of the solid particles existing in the air of all ordinary localities.* The best evidence, however, in proof of the view that they are products of a development which has taken place within the crystal would be, if it could be shown that in a given batch of recently prepared crystals no such organisms were to be found, whilst in many other crystals belonging to the same batch, after an interval of weeks or months, the spores and filaments were to be discovered. Sufficient time has not yet elapsed to enable me to speak definitely on this subject. This much, however, I can say. Certain of the crystals of the batch prepared for me by Messrs. Hopkin and Williams, when examined two days after preparation, were found to contain scarcely a trace of air within. Now, however, after an interval of three weeks, through which they have been kept during the day-time at a temperature of about 80° Fahr., certain other of these crystals do, when dissolved, give exit to a notable quantity of air bubbles. This seems to indicate pretty clearly that a change of some kind has been taking place in the material of the crystal, which has led to the liberation of some of its constituents in a gaseous condition, and also, perhaps, to a liberation of some of its water of crystallisation. Whilst this has been taking place, its other elements may have been grouping themselves anew. Although, at present, there is still no certain trace of the spores or filaments, I am strongly disposed to expect that such organisms will manifest themselves in the course of a few weeks more.

[Two weeks after writing the above paragraph, and whilst these proofs were going through the press, on June 9 I examined three more specimens from the recent batch of crystals which had been set aside for observation. The quantity of gaseous bubbles which escaped from within the crystal seemed almost equal to those which had been met with within the older crystals. One or two small fragments of cotton also emerged, and in addition several very small masses of a transparent mucoid material, containing refractive protein-looking granules of various sizes and shapes. These were almost precisely similar to masses which had been met with in the older crystal. Here and there an early stage, or short portion, of a filament was seen amongst the granules, though none of these were sufficiently long to make me certain as to their nature and affinities. Although nothing else was found, the occurrence of the very small masses of mucoid material seemed to represent a stage in advance of what was met with at the last examination. One of these small mucoid masses I saw within an elongated cavity (near the surface of a half dissolved crystal), two-thirds of which was occupied by a large bubble of gas. Whilst the crystal was still under the microscope, I saw the bubble and the small mucoid mass emerge from the cavity.]

Assuming, then, the view which seems most probable, that the spores and filaments have grown within the crystal—that they are the developed representatives of certain specks of Living matter—two views may still be taken as to the origin of such Living specks. Either (1) these are some of the pre-existing "germs" of the panspermatists which have become mechanically enclosed within the crystal, or (2) these Living specks have been therein evolved by virtue of certain changes and re-arrangements which have taken place amongst the non-living constituents of the crystalline matter.

Of these two alternative views I am, after reflection on the following considerations and evidence, strongly inclined to believe that the latter is most probably the true one:—

(*a*.) It must be remembered that however strange and unlikely a situation the interior of a crystal may appear for the evolution of organisms, there is the strongest reason for believing that cavities are formed within crystals of tartrate of ammonia,†

* In all my investigations I have never met with spores *similar* to these except in one or other of the ammoniacal solutions.

† The gases which appear in bubbles increase in quantity with the age of the crystal, and these gases have been seen to be lodged in cavities within the crystal. These cavities are, perhaps, more especially liable to

and there is almost as much reason for believing that the confervoid-looking filaments and the fungus-spores have undergone a process of *growth* and *development* within such cavities. Other facts, which seem to lend an increased probability to this supposition, will shortly be detailed. But if "the conditions" are favourable enough to permit, or even to stimulate the molecular activity of certain Living particles, and if such molecular activity, whereby the Living speck grows and developes, is but the modified manifestation of the physical forces acting thereupon, I see no theoretical reason why the self-same physical forces acting upon the self-same materials should not have been able, in the same place, to *initiate* a molecular collocation similar to that which they now help to build up from moment to moment. We have been, perhaps, only too much in the habit of looking upon this as impossible. But let us sweep away this habit of mind for the moment, let us look at the facts as they are, and will it be at all easier for us, who believe in no special "vital principle," to understand how from moment to moment non-living matter is converted into matter which lives? However little we may understand it, this process is continually taking place in all growing representatives of the vegetable kingdom, and no one ever thinks of doubting that it does take place because he is unable to understand *how* it occurs. If it were once conceded that a *de novo* evolution of specks of Living matter were possible, then I think most physiologists would at once admit that where specks of Living matter are able to grow and develope, there also they may be quite capable of originating.

(*b.*) The matter of the crystals of tartrate of ammonia is, by a re-arrangement of its atoms, quite capable of giving origin to organisable compounds. If a small quantity of tartrate of ammonia is dissolved in a watch-glass with distilled water, and is protected as much as possible from dust and evaporation by being covered with a wine-glass from which the stem has been broken, and then again with a tumbler, it will be found during warm weather, that in the course of two or three days the bottom of the watch-glass is covered by a number of minute microscopic crystals, interspersed amongst a mixed layer composed of monads, bacteria, and minute *Torula* cells.* These organisms form, in fact, almost as freely (though more slowly) in the ammoniacal solution, as they do in an ordinary infusion containing organic matter. There can be little doubt that the amount of ammonia and of tartaric acid actually diminishes, and that the elements of these enter into new combinations.†

It may be said, however, that such changes do not take place by the mere action of physical forces upon the unstable molecules of the dissolved tartrate of ammonia, and that *Living ferments* are necessary for the initiation of such molecular re-arrangements. In answer to this I can only call attention to the fact that similar changes must have taken place in the fluids within the experimental tubes which were submitted by Dr. Frankland to a temperature varying from 146° to 153° C. for four hours, and that there is not one tittle of evidence at present existing to show that any Living thing could live through such an exposure, whilst there are very strong reasons indeed which should incline us to believe that no Living thing could be subjected to such a temperature without being hopelessly destroyed. Therefore in these cases it would appear that such molecular re-arrangements must have been initiated without the intervention of Living ferments, and thus, too, they would appear to be comparable with those that are known to take place in a solution of cyanate of ammonia. Here "spontaneously," or with the aid of a little heat only, a molecular re-arrangement occurs, and the saline cyanate of ammonia is replaced by a colloidal compound, urea. In order to effect this transformation, no Living ferments are necessary—none have been even supposed to exist, and there is, really, no more reason why we should imagine their presence to be necessary in order that tartrate of ammonia may undergo a more or less similar isomeric transformation.

A careful examination of the mode in which bacteria and *Torula* cells appear at the bottom of a watch-glass containing tartrate of ammonia in solution is also rather valuable on account of its bearing upon this question. What is true of the *Torula* cells is also true concerning the mode of origin of bacteria; the facts, however, can be ascertained rather more satisfactorily concerning the *Torula* cells, and for the sake of brevity I shall now speak only of them. These *Torula* cells, like the bacteria in their earlier stages, are motionless; although, therefore, they increase rapidly after one or more have been formed by a process of pullulation and growth, the numerous quite distinct patches which may be seen scattered over the bottom of the watch-glass, often at well marked distances from one another, represent so many distinct centres of origin. In these several patches there may be seen delicate ovoid *Torula* cells of almost any size beneath $\frac{1}{8000}''$ in diameter. The larger cells exist united in little groups of twos and threes, and budding from them may be seen pullulating projections of different sizes. Separate cells, also, may be seen, smaller and smaller in size, till at last they cease to be cellular in form, and we see only peculiarly refractive dots or specks less than $\frac{1}{60000}''$ in diameter. In other places a colony of *Torula* cells seems to be about to grow up. Here there may be seen merely one or two of the smallest bodies which distinctly display the cellular form interspersed amongst a variable number of the refractive specks of all sizes down to the *minimum visible* stage.* Beyond this, of course, all is darkness. We must be guided by other evidence in forming an opinion as to the probable source or mode of origination of these specks of Living matter, which are so extremely minute that they only just come within the range of our aided vision.

Another remarkable observation made upon a simple solution of carbonate of ammonia, in a watch-glass, makes still clearer the fact of the disseminated origin of organisms in such solutions. It throws light also upon the previous question as to whether the fungus-spores were developed within the crystals of tartrate of ammonia from specks of Living matter, or whether they were mechanically enclosed in their developed form; and it is sufficiently suggestive as to the possible influence of electrical conditions in promoting evolutional changes. Referring to notes made at the time, I extract the following particulars. About eleven P.M. on the 14th of the present month (June) a small quantity of ordinary sesquicarbonate of ammonia was dissolved in some apparently pure (though not distilled) water, in a watch-glass. After solution, and in about an hour's time, the fluid was carefully examined with different microscopic powers, and lastly the bottom of the watch-glass was scrutinised in very many situations with an immersion $\frac{1}{12}''$ object-glass. No Living thing of any kind was seen, though scattered over the bottom of the glass were a large number of tiny crystals, some larger and some smaller than $\frac{1}{3000}''$ in diameter. Under the polariscope they gave the most beautiful and varied colour reactions. The watch-glass was then placed on a mantel-piece with a soft surface (covered with velvet), a wine-glass, with its stem broken off, was inverted over it, and this again was covered by a tumbler, in order, as much as possible, to prevent evaporation and keep out dust. After twenty-four hours the bottom of the watch-glass was again carefully examined, with the $\frac{1}{12}''$ object-glass, and no change was observable. There were the same minute crystals, perhaps rather more numerous than before, but no recognisable specks of protoplasm or other trace of living things. The watch-glass was then replaced as before. The next day (June 16) the weather was hot and extremely sultry. The temperature was about 85° F. in the shade, and the thunder-storm, which seemed imminent during the whole of the day, began about 7 P.M., and continued till the early hours of the morning of the following day. At about 11.30 P.M. of this 16th of June, I again examined the solution in the watch-glass—forty-eight hours after it had been prepared. Then, scattered over the whole of the bottom of the glass, fungus-spores were seen in all stages of development intermixed with the small crystals. They were quite motionless, and mostly separate, rather than in distinct groups. They varied in size from the minutest visible speck up to a spherical nucleated body $\frac{1}{3300}''$ in diameter. No moving particles or bacteria were seen. Probably more than a thousand of these bodies were developing in the one watch-glass—each growing in its own place, and showing no evidence of multiplication by division or pullulation. Until they attained the

form in those crystals which are not perfect in shape, and which present a more or less opaque appearance in their interior. These less perfect types are probably for that reason more prone to undergo molecular changes under the influence of incident forces, especially in the neighbourhood of and around some fibre-fragment which has been enclosed.

* In saline solutions I have generally seen the organisms first, and have found them accumulated principally at the *bottom* of the watch-glass or other vessel in which the solution may have been contained.

† Saline solutions in which spores of fungi were placed, having been analysed previously by M. Pasteur, were again analysed by him after the plants had grown for a time. The proportion of ammonia and of other ingredients was found to have undergone a diminution correlative with the growth of the plants.

* When such a patch is marked, and watched at different intervals, a crop of perfect *Torula* cells is soon seen to occupy this same situation. And it may be well to state here that *Sarcina* also makes its appearance after a fashion which is essentially similar.

size of about $\frac{1}{10000}''$ in diameter no nucleus was visible, though they had by this time assumed a distinctly vesicular appearance. As the spores increased in size, the thick wall gradually became more manifest—though it had a rather rough granular appearance—and a nucleus gradually showed itself within, which was also granular.* The next morning, after twelve hours, the spores seemed to be much in the same condition, though numerous small colonies (30 to 50 in each) of motionless bacteria were now visible. During the day the air was clear, and the temperature lower (76° F.); and after twelve hours more (in

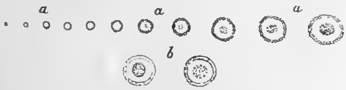

FIG 19.—Representing different stages in the development of Fungus-spores in a solution of Carbonate of Ammonia.

the evening) the bacteria were found to have considerably increased in number, and several of the fungus-spores were seen in a more devoloped condition—their thick walls being wholly or partially consolidated, and the nucleus was also more distinctly defined. In this condition they perfectly resembled the spores which were found in *Experiment* 20, and very closely resembled those which are to be met with in some of the old tartrate of ammonia crystals. The great majority of the spores were, however, still in the granular condition, and they seemed to have made no advance whatever. On the following day these spores were not quite so distinct—some of them seemed to be disintegrating, whilst none of them had undergone any further development. The bacteria, on the contrary, had decidedly increased in quantity. After two days more, minute *Torula* cells began to appear. These did not rapidly multiply, but soon began to develope into mycelial filaments.

The thick-walled spores had possibly come into existence under the influence of the high temperature and the disturbed electrical condition of the atmosphere †; and they seemed to be so much the creatures of these conditions that they were unable to survive under others which were different.

The mode, then, in which fungus-spores make their appearance in a solution of carbonate or tartrate of ammonia, seems to show that they must have originated in all parts of the solution, either by a coalescence and re-arrangement of the invisible molecules of a *pre-existing* colloidal compound,‡ or else through the development of innumerable but invisible "germs," which were disseminated through the liquid. That such invisible "germs" may have existed in the form of colloidal molecules, I am quite disposed to believe—though I am as strongly inclined to disbelieve that these fluids were saturated with "germs" of veritable fungus-spores, which had emanated from some pre-existing fungus of the same kind. We may grant that germs were there *in posse*, though not *in esse*. What warrant have we, indeed, for talking of actual though *invisible* fungus "germs"? No one can know more concerning their existence or formation than I know concerning the coalescence of colloidal molecules into minutest specks of Living matter. The necessity for the postulation of such "germs" must, therefore, seem different to different people, in accordance with the particular views which they may hold concerning Life. Those who believe in a special "vital principle" may naturally enough cling to the notion of a pre-existing germ, which may be the direct recipient of this peculiar power from some pre-existing organism; whilst those who are believers, rather, in the physical doctrines of Life will, I think, gradually find themselves contented with the pre-existence of potential "germs" in the form of colloidal molecules.

* This appearance I had not unfrequently seen before, where such spores had been developing in saline solutions, and it had always strongly suggested the notion to me that these spores were formed by a coalescence of granular particles. Here, however, there were no granules or moving particles present, the spores themselves were the only Living things, and it seemed quite certain that they could not have originated after this fashion. They obviously commenced as minute specks, and the granular appearance manifested itself so long as they were still increasing in size. When growth stopped consolidation began to take place, and an even double-contoured wall soon replaced that which was before irregular and granular.

† We may, perhaps, connect this possibility with the well-known fact that milk, beer, and other fluids are so very prone to turn sour during a thunder-storm, or whilst it is threatening.

‡ One which had existed before the organisms made their appearance, but which was the product of an isomeric modification of the carbonate of ammonia itself.

(*c*.) We find, also, associated with different sets of conditions, different kinds of Living things. In none of the crystals of tartrate of ammonia have I ever found a single distinct bacterium, and there has been the same complete absence of organisms of this kind in all my experimental fluids containing tartrate of ammonia and phosphate of soda, which have been sealed up *in vacuo*. This agreement is very striking, seeing that whenever a similar fluid, or a solution of tartrate of ammonia alone, is exposed to the air, then bacteria appear in abundance.* There is a marked accordance then between the organisms which are produced in the experimental tubes *in vacuo*, and those which come from the cavities within the crystals. There is the strongest reason for believing that the organisms which were met with within one of these experimental tubes must have been evolved *de novo*, since the existing state of our knowledge does not entitle us to believe that any such pre-existing Living thing could continue to live after it had been exposed to a temperature of from to 146° to 153°C. for four hours; and so we derive an additional presumption in favour of the *de novo* origination within the crystals, of those minutest specks of Living matter, which, as we have seen, are capable of developing into such fungus-spores as are there to be found.

In the face of this much more severe test (*Experiment* 19) it is needless to insist upon the results of other experiments in which the solutions were merely exposed to a temperature of 100°C. The fungus-spores which exist within the crystals of tartrate of ammonia do not differ, however, from all other fungus-spores that have been made the objects of experimentation. They too will not germinate after they have been exposed for one minute to a temperature of 100°C. I have taken spores and filaments from a crystal, and one half of them I have boiled for about a minute whilst the others have not been heated at all. The two patches have then been placed, at some little distance from one another, in the same growing box, with a few drops of a solution of tartrate of ammonia. The spores which had been boiled did not germinate, but those which had not been heated soon began to develope filaments. The pre-existing confervoid-looking organism, also, in the one case underwent no change, whilst in the other it grew into a distinct fungus—its filaments widening out till they became about four times as broad as they were originally. These unmistakeable fungus-filaments showed dissepiments at intervals dividing them into chambers, within which were contained large irregular blocks of protoplasm. Occasionally a filament larger than the others, might be seen terminating with a broad convex extremity, and afterwards there gradually appeared on the surface of this the minutest dot-like projections, which slowly increased in size and number. The larger of them soon became vesicular, and after a time within the vesicle granules began to cluster so as to constitute a nucleus. Thus were watched the early stages of the development of a head of fructification similar to, although much smaller than that which is represented in Fig. 17. The rate of growth was generally very slow, and after a time development ceased in my growing box, apparently because the conditions were not suitable for the evolution of such an organism as did grow luxuriantly enough within my experimental flasks. These observations were, however, extremely interesting, because I was thus able to trace all the stages in development, on one and the same plant, from mere granular abortive-looking *Leptothrix* threads, only $\frac{1}{20000}''$ in diameter, which gradually grew into a distinct confervoid-looking tube, having broken masses of protoplasm within, into slowly widening and dissepimented fungus-filaments, that were capable

* There is another difference also which deserves to be pointed out. The crystals of tartrate of ammonia or of phosphate of soda have never shown a trace of the Spiral-fibre organisms or of *Sarcina* (Fig. 13 *d*), and yet when the two have been mixed, in several of the fluids which have been kept *in vacuo*, the Spiral-fibre organism has appeared, and, similarly, on two out of three occasions when this mixture has been exposed to the air *Sarcina* has made its appearance. In one of the solutions *in vacuo* containing carbonate of ammonia and phosphate of soda, a somewhat similar Spiral-fibre has been found, and in the other *Sarcina* was met with. Both these organisms therefore seem dependent upon the presence of phosphates, and it is worthy of note that hitherto *Sarcina* has, so far as I am aware, never been known to exist except in one of the fluids of the animal body where phosphates naturally or unnaturally are present. At first *Sarcina* was discovered by Goodsir in the contents of the stomach, then it was found in the urine, and afterwards within the ventricles of the brain by Sir Wm. Jenner. And now I meet wth it in solutions containing an ammoniacal salt and a phosphate. M. Pasteur has (Ann. de Chim. et de Phys., 1862, Pl. II., fig. 27, K., and p. 80) figured, and alludes to an "Algue formée de cellules quaternaires, déposée sous forme de précipitate," upon the walls of a flask which had contained "l'eau de levûre non sucrée," and which certainly, if not *Sarcina*, must be very closely allied thereto.

of producing a head of fructification of the *Penicillium* type. Thus, in fact, there appeared to be a strong tendency in the *Leptothrix* filaments and in the loose spores found within the crystal, to develope into the same kind of organism when either of these was placed under the influence of other and more suitable conditions. In the crystal itself, apparently, just as the conditions were not suitable for the germination of the spores, so they were not favourable for the developmental conversion of the confervoid-looking filaments into a fungus.

Whether there was any genetic relationship existing between these confervoid-looking filaments which commenced life as *Leptothrix* threads, and the few scattered spores which were frequently found with them within the crystal, is not quite certain. If any relationship did exist, however, it could only have been of one kind: the spores may have been descendants from the matter of the filaments, but the filaments were most certainly not developments from the spores. The spores existed singly or in groups of twos and threes. They were never seen in organic connection with the filaments, so that I am inclined to believe they were not even formed by a process of budding. They must, then, either have derived their origin from a minute speck of the matter of the filament which subsequently grew into a spore,* or they must have been evolved *de novo* where they were found, just as we are compelled to imagine that the similar spores must have been evolved *de novo* within the flask used in *Experiment* 19, at first by a coalescence and re-arrangement of colloidal molecules, and subsequently by a process of development similar to what is represented in Fig. 19. And, if the fungus-spore and the confervoid-looking filament both tend towards the same ultimate developmental form, we can only attribute this to the fact of the existence of a harmony between the "conditions" and such an organism. The confervoid filament and the fungus-spore are both produced within the same crystal: they seem to be but different products of what appears to us to be the same matter and the same "conditions," and if minute differences may have existed at first tending to make the initial modes of development different, the main intrinsic similarity manifests itself at last by leading them both along a line of development which terminates in a common organic form.†

For these various concurrent reasons, therefore, I deem it much more probable that the filaments and spores found within the crystals of tartrate of ammonia have been developed from specks of Living matter there evolved *de novo*, rather than that they have originated from germs of similar pre-existing organisms which had accidentally been enclosed within the crystals.

Before closing this paper, it will be necessary that I should refer more particularly to a certain part of M. Pasteur's researches, seeing that these have so strongly influenced the opinions of very many scientific men on the question of the truth or falsity of the doctrines of the heterogenists. As an experimental chemist, M. Pasteur takes a most honourable position in the foremost rank of workers, and all his investigations on this subject appear to have been conducted with the most scrupulous care. His reasonings, also, may seem at first sight to be all convincing, so that most people might be inclined to admit that he had "mathématiquement demontré," as he so frequently claims to have done, all that he had set himself to prove. The case may seem at first a poor one indeed for the heterogenists; but as soon as one gets over the first impressions produced by the various experiments, and begins to inquire whether the reasonings concerning them have been in all cases fair and logical, then it may be seen that the evidence against the occurrence of heterogenesis is very far from being so strong as it, at first sight, appeared.

On two or three occasions, when it was very important that results should be looked at from different points of view, M. Pasteur has altogether failed to do this, and has wished to interpret them only in accordance with the views of the panspermatists, *quietly ignoring the equally legitimate interpretation of the same results which might have been given by the heterogenists.* At present I shall confine myself to one instance of this kind, because I think that on this particular point the reasonings of M. Pasteur are as mischievous as they are illogical. If others were to follow his example, then certainly we could never hope to get rid of the clouds of controversy which at present obscure this subject.

The experiments of Schwann were for some time erroneously believed by very many to have upset the doctrines of the heterogenists. No organisms, it was said, were ever developed in hermetically sealed vessels when the solutions containing the organic matter had been boiled, and when all the air which was allowed access to them had been previously calcined. Schwann's experiments did yield uniformly negative results when solutions of meat were employed; though his experiments concerning alcoholic fermentation yielded results which were sometimes positive and sometimes negative. M. Pasteur also, for a time, obtained only negative results in repeating the experiments of Schwann. In these experiments, however, he had generally made use of "l'eau de levûre sucrée," of urine, or of some other fluid which was naturally unfitted to undergo evolutional changes of a high order, or even to produce lower organisms in great abundance.* But there came a time when M. Pasteur chanced to repeat his experiments, using precisely the same precautions as before, and yet the results were quite different—organisms were now found in his solutions. There was one important difference, it is true. In these latter experiments, M. Pasteur had made use of milk. Now the quantity of organic matter contained in milk is, of course, very great; it is a highly nutritive and complex fluid. It might, therefore, and ought, perhaps, to have suggested itself to M. Pasteur that the different results of his later experiments were possibly explicable on the supposition that the restrictive conditions—the boiling of the solution and the closed vessel already containing air—were too potent to be overcome by the organic matter in the one solution, whilst they were not too potent and could not prevent evolutional changes taking place in that of the other. For if, in accordance with the belief of the evolutionists, different organic fluids have different initial tendencies to undergo the changes of evolution, it may be easily understood that as the conditions favourable to evolution are more and more restricted, certain of these fluids may altogether cease to undergo such changes, others may manifest them to a meagre extent, and others still, only a little more fully. Therefore, if under the conditions peculiar to Schwann's experiments, certain fluids with low evolutional tendencies have given rise to no organisms, there is nothing whatever contradictory in the fact if it is subsequently ascertained that other fluids, with greater inherent capacities of undergoing change, will, notwithstanding all the restrictive conditions, pass through certain Life-producing changes. When subjected to a pressure of one atmosphere, water boils at 212° F., alcohol at 173° F., and ether at 96° F. The restrictive condition, or atmospheric pressure, is here in each case the same, only, having to do with differently constituted fluids, it is natural enough to look for different results under the influence of like incident forces. Ether raised to a temperature of 100° F. would rapidly disappear in the form of vapour, though no such result would follow the heating of water to a similar extent. And similarly, whilst milk might be capable of yielding organisms in Schwann's apparatus, another fluid less rich in organic matter might fail to do so. It seems almost incredible that such considerations should not have suggested themselves to M. Pasteur; but yet we have no evidence that they did occur to him.† On

* A mode of origin of spores which is, I believe, quite familiar to fungologists.

† This form of fungus-spore seems to be most prone to occur where different ammoniacal salts are employed. It has been met with not only in the tartrate of ammonia solutions, but also in those containing oxalate of ammonia and carbonate of ammonia respectively. And it has been found in no other of my experimental fluids.

* In order to avoid circumlocution in this note, I speak from the evolutionist's point of view. And whether the organisms found in a given fluid have been actually produced therein, or have only there undergone development, we may, for the sake of argument, measure the evolutional capacity of a fluid by the amount and kinds of organisms which are produced in a given quantity of it, in a definite time, and at a given temperature. We must not, however, judge of the evolutional qualities of a fluid by its mere tendency to emit a bad odour in a short space of time. A certain fluid—urine for instance—judged by these qualities, may be disagreeably putrescible, though its evolutional tendencies may be quite low. By many experimenters this difference has not been appreciated, and they seem to imagine that in employing urine they make use of a fluid which is very favourable for such experiments. But they forget that urine is an effete product containing comparatively stable compounds, which have already done their work in the body. It may after a short time swarm with bacteria, and these may be followed by fungi; but there is no comparison between the actual quantities even of these organisms, which will be developed in equal amounts of milk and urine respectively, when they are both exposed to the air for the same time in similarly-shaped vessels, and under the same bell-jar. The milk soon becomes actually solid with fungus growths. M. Pasteur's "l'eau de levûre sucrée," by his own confession (*loc. cit.* note, p. 58) is never found to contain any of the higher ciliated infusoria, and in all probability, though it produces fungi, these are met with in much smaller quantity than they would have been in an equal bulk of milk under the same conditions.

† The experiments and reasonings to which I am now alluding are detailed in pp. 58—66 of M. Pasteur's Memoir (*Ann. de Chim. et de Phys.* 1862).

the contrary, he explains the discrepancy between his earlier and his later experiments by another supposition altogether. As on other occasions, he does not even suggest to the reader that any different explanation is possible from that which he adduces. He deliberately assumes that the bacteria and vibrios which were subsequently found in the milk used in these experiments had been derived from "germs" of such organisms which either pre-existed in or had obtained access to this fluid before it had been heated, and also (contrary to the general rule which had been previously admitted) he assumed that such supposed pre-existing germs were capable of resisting the influence of the boiling temperature in milk. No direct proof of the latter assumption was ever attempted, though M. Pasteur did afterwards endeavour to bring these exceptional cases under a general law by supposing that the results obtained were due to the absence of acidity in the fluids employed. Neutral or slightly alkaline fluids might, he thought, yield positive results in Schwann's experiments, because the germs of bacteria and vibrios were not destroyed, by the boiling temperature in such fluids.

Such was the very definite statement made by M. Pasteur on the faith of a chain of evidence almost every link of which is ambiguous. The most direct observations, however, which can be made upon this subject (and to the desirability of making which he does not even allude) lend not the least support to his assumption. On the contrary, they go to confirm the rule which had hitherto been generally admitted as to the inability of any of these lower organisms to live after an exposure for even a few seconds in a fluid raised to a temperature of 100°C. I have again and again boiled neutral and alkaline infusions containing very active bacteria and vibrios, and the result has always been a more or less complete disruption of the vibrios, and the disappearance of all signs of life in the bacteria. All their peculiarly vital movements have at once ceased, and they have henceforth displayed nothing but mere Brownian movements.*

M. Pasteur approaches the solution of the discrepancy in this way. His attention was arrested by the fact that milk was an alkaline fluid, because he afterwards ascertained that other alkaline fluids also yielded positive results when submitted to the conditions involved in Schwann's experiments. Thus he himself helped to overturn the strongest evidence which had hitherto been brought to bear against the heterogenists. But, this being done, it was necessary for M. Pasteur to explain such an occurrence, if he was not prepared to yield his assent to the doctrine which he had formerly rejected. He now found, truly enough, that the mere alkalinity or acidity of the solution was a matter of great importance in these experiments; he found, for instance, that his "l'eau de levûre sucrée," naturally a faintly acid fluid, was always unproductive when submitted to Schwann's conditions unaltered, though it was, on the contrary, always productive if it had previously been rendered neutral or slightly alkaline by the addition of a little carbonate of lime. Facts of this kind were observed so frequently as to make him come to the conclusion that whilst acid solutions were never productive in Schwann's apparatus, any neutral or alkaline fluids might be, if it were otherwise suitable for such experiments. Then came the question as to how this was to be explained. It should be remembered that M. Pasteur was engaged in investigating the problem of the mode of origin of certain low organisms in organic fluids, concerning which so much controversy had taken place. In this controversy, hitherto, on the one hand, it had been contended that the Living things met with derived their origin from pre-existing "germs" that had survived all the destructive conditions to which the media supposed to contain them had been subjected; whilst, on the other hand, it was contended that if the media had been subjected to conditions which (by evidence the most direct and positive) had been shown to be destructive to the lowest Living things, then such Living things as were subsequently discovered in these fluids must have been evolved *de novo*. It was a question, therefore, on the one hand, as to the degree of vitality or capability of resisting adverse conditions peculiar to the lowest Living things; and, on the other, as to the strength of the tendency to undergo changes of an evolutional character in the organic matter existing in the solutions, and on the degree to which this molecular mobility could persist, in spite of the disruptive agency of the heat to which the organic matter might be subjected. When, therefore, after having been exposed to a given set of conditions, organisms are not subsequently found in the fluids employed, this is explicable in one of two ways—that is, in accordance with either of the two opposing views. Either the heat has proved destructive to all Living things in the solutions; or else the restrictive conditions to which the organic matter in the solutions has been exposed have been too severe to permit the occurrence of evolutional changes therein. Any person seriously wishing to ascertain the truth, and competent to argue, of course would not fail to see that he was bound to give equal attention to each of these possibilities. He had no right to *assume* that the probabilities were greater in favour of the one mode of explanation than they were in favour of the other; this was the very subject in dispute—this, it was, which had to be proved. When, therefore, it was definitely ascertained by M. Pasteur that acid solutions employed in Schwann's experiments yielded negative results as far as organisms were concerned, the establishment of this fact was in reality no more favourable to the one view than to the other. It is what the Panspermatists might have expected, it is true, because—regarding it only as a question of the destruction or non-destruction of germs—even they had convinced themselves that calcining the air and boiling the fluids were adequate to destroy all Living things contained in these media; but, on the other hand, it was equally open to the Evolutionists to say that—the restrictive conditions employed being so severe—they also were not surprised at the probable stoppage of evolutional changes and at the consequent non-appearance of organisms in the solutions. When positive results were obtained, however, the case became altogether different. The rule being absolute, so far as it had gone—and founded on good evidence, to which M. Pasteur and others had assented—with regard to the inability of Living things to survive in solutions after these had been raised to the boiling temperature for a few minutes; no one should have attempted to set aside this rule, except upon evidence equally direct and equally positive, though more extensive, than that upon which the rule had been originally founded. Certainly, no one should have attempted to set it aside on the strength of *indirect evidence, which, though equally capable of explanation in accordance with either one of the two opposing views, was tacitly represented to be explicable only in accordance with one of them.* Such, however, has been the conduct of M. Pasteur. It will, perhaps, scarcely be credited by many that the investigations of M. Pasteur, which have had so much influence, and which have been looked upon by many as models of scientific method, should really contain such fallacies. On other important occasions, however, his reasoning has been similarly defective, though he himself claimed and was believed by many to have "mathematically demonstrated" what he had so plausibly appeared to prove.*

In the present case, after his experiments with milk in Schwann's apparatus, M. Pasteur ascertained that in other alkaline or in neutral fluids, even when they had been subjected to all the conditions above mentioned, inferior organisms might be found more or less quickly. But he also discovered that even such solutions no longer yielded organisms if, instead of subjecting them to a heat of 100° C. they had been exposed for a few minutes to a temperature of 110° C. And it was on the strength of two or three other links of such evidence as this that M. Pasteur sought to upset the rule with regard to the inability of inferior organisms to resist the destructive influence of a moist temperature of 100° C. On such evidence as this he attempted to raise the possible limit of vital resistance by 10° C., and sought to establish the rule that Living organisms might survive in neutral or alkaline solutions if these had not been raised to a temperature of 110° C. He did not seem to see how utterly inconclusive his conclusions were, and that he had not so much right to assume that the organisms met with in his neutral or alkaline fluids had been derived from "germs" which had resisted the boiling temperature, as he or his opponents would have had at once to fall back upon the counter assumption that the evolutional tendencies of neutral or alkaline fluids exposed to high temperatures were greater than those of similar fluids when in an acid state—and that such neutral or alkaline fluids were, as was now seen, capable of overcoming the restrictive conditions in Schwann's experiments and of giving birth to organisms, by permitting the occurrence of Life-evolving changes amongst the colloidal molecules contained therein. He had less right to explain the facts as he did, than the evolutionist would have had to explain them as above mentioned, because he was thus attempting to upset

* See what has been previously said on this subject (p. 171).

* The space at my disposal does not permit of my alluding to these other occasions at present, though I shall do so in my forthcoming work.

previously admitted facts on insufficient evidence, whilst the reasonings of the evolutionist would have been in every way legitimate. And yet M. Pasteur left his readers to imagine that the explanation which he had adduced was that which was alone admissible; he did not refer to the existence of any other mode of explanation, but at once attempted to set aside the old rule. And similarly, when he ascertained that such alkaline or neutral fluids were no longer found to contain organisms if they had been previously submitted to a temperature of 110° C. he was entitled to draw no conclusion from such facts. Nevertheless, M. Pasteur did assume that such indirect evidence entitled him to come to the conclusion that the hypothetical "germs" contained in these solutions—those which were not killed, as he supposed by a temperature of 100° C, were destroyed by a temperature of 110° C. Such two-faced evidence is, however, worthless for raising the standard of vital resistance; and to ignore the possible differences which may exist, from the evolutionist's point of view, between acid and alkaline solutions, as M. Pasteur did, is about as reasonable as if he had imagined that because water does not boil at the temperature of 100° F. the same rule must necessarily hold good for ether.

Much evidence, indeed, can be brought forward to show that even at ordinary temperatures, and under conditions in which there is a moderately free exposure to the air (and, therefore, with every facility for the entrance of "germs"), a neutral or slightly alkaline solution is not only found to contain organisms more quickly, but these are found to exist therein in much greater variety than in solutions in other respects similar, save for the fact of their being slightly acid rather than alkaline or neutral. Any of the higher forms of ciliated Infusoria *may* appear in different neutral or slightly alkaline solutions, though they never present themselves in those having an acid reaction, and *neither are their undeveloped ova or their dead bodies to be found therein.* The amount of difference capable of being produced by the mere acidity of a solution was well seen by me a few months ago. Having prepared * a mixture of white sugar and tartrate of ammonia, with small quantities of phosphate of ammonia and phosphate of soda in distilled water, whose reaction was found to be neutral, two similar wide-mouthed bottles of about three ounces capacity were filled with the fluid. Both were kept side by side in a tolerably warm place, the mouths of the bottles being merely covered in each case by a piece of glass, after glycerine had been smeared over the rim on which the cover rested. Although not hermetically sealed, these solutions were thus sufficiently protected to prevent the access of much dust from the neighbouring fire. The fluid in the one bottle was allowed to remain neutral, whilst to that of the other four or five drops of acetic acid were added, so as to make it yield a faintly acid reaction to test paper. The results were quite different in the two cases. Towards the end of the fourth day the originally unaltered neutral solution began to assume a cloudy appearance; this increased in amount during the next day, and at the close of the sixth day a thin pellicle was found on the surface, and beneath it there were some irregular, flocculent, whitish masses buoyed up by small air bubbles. Examined microscopically, the pellicles and also the flocculent masses beneath were found to be made up of medium-sized monads and bacteria, mixed with crystals of triple phosphate. There were also many scattered cells of a *Torula*, varying from $\frac{1}{5000}''$ to $\frac{1}{10000}''$ in diameter. By this time (close of the sixth day), however, the companion solution which had been slightly acidified, had undergone scarcely any appreciable change. It was still quite clear and transparent, and there was no pellicle on the surface, though there was a very slight whitish flocculent stratum at the bottom of the bottle. Even on the twenty-first day this solution continued in much the same condition—still showing no trace of a pellicle. The fluid itself was clear, and there had been only a very slight increase in the thickness of the white flocculent layer at the bottom of the bottle, which, on microscopical examination, was found to be made up mainly of a granular matter having no definite character—though mixed with this there were a small number of minute but well-formed bacteria. This acid solution had remained throughout in the same warm place, but the bottle containing the neutral fluid had not (after the examination on the sixth day) been replaced in its original place near the fire; it had continued since this time in a part of the room altogether away from the fire, and yet when this also was examined on the twenty-first day, it was found to present a very cloudy, whitish appearance throughout, there was a thick flocculent stratum at the bottom, and also a very consistent, well-marked pellicle on the surface of the fluid, made up almost entirely of large and well-formed *Torula* cells.

Although the results here detailed, as occurring in the neutral and the acidified solutions respectively, are so strikingly different, still they are by no means singular or peculiar to the particular kind of solution which was employed in this experiment. Phenomena essentially similar in kind may be observed when almost any neutral or slightly alkaline organic infusion is employed. Thus, to quote one only out of many experiments bearing upon this point. A short time ago, having prepared a pretty strong infusion of mutton, about an ounce and a half was put, after filtration, into each of two similar flasks. The one portion of the infusion was allowed to remain neutral, whilst to the other were added three drops of strong acetic acid, so as to make the whole yield a faintly acid reaction to test paper. The two flasks were then exposed side by side to a temperature of 75° to 80° F. during the day. In twenty-four hours time the neutral solution was clouded and more or less opaque, whilst the portion which was acid appeared perfectly unchanged. It was as clear as ever; and so it continued even to the end of forty-eight hours, although by this time the neutral solution was quite opaque, muddy-looking, with a pellicle on its surface, and also some flocculent deposit at the bottom of the flask. A microscopical examination of two or three drops of this fluid showed that it was teeming with most actively moving monads, bacteria, and vibrios, whilst a similar examination of the acid fluid showed not a trace of these or of any other kinds of organisms.*

The difference between the results in these two sets of cases was thus extremely well marked, and the results themselves are well worth our serious attention. We had to do with equal bulks of fluid, placed under similar conditions and similarly constituted, with the exception that in each set a few drops of acid had been added to the one fluid, whilst the other was allowed to remain neutral. And it must be confessed that the difference encountered was very similar in kind to that which was observed by M. Pasteur when he made use of acid, or of neutral or alkaline solutions respectively, in repeating the experiments of Schwann. Only here we have had nothing to do with the destructive agency of heat, and germs were as free to enter into the one solution as they were into the other, so that the differences actually observed would seem now, at all events, due simply to the different qualities of the fluids themselves. Of course, such results cannot be adduced as evidence that the evolutional property of the neutral solution was higher than that of the acid solution. It may be not a case of evolution at all, but simply one of growth and development. The results, however, do show plainly enough that the neutral solution was the one most favourable to the growth and development of Living things. And if, starting from this fact, which cannot be denied, the evolutionists see reasons which induce them to assume the possibility that, in addition to mere growth and development, an actual origination of Living things may have taken place *de novo*, they would also be likely to suppose that the neutral fluid was more favourable to such evolution than that which had been acidified.† That solution which was found favourable for the processes of growth and development would also, in all probability, be favourable for evolution. A process would be most likely to be *initiated* where the conditions were suitable for its continuance. And surely the same factors would be at work in the initiation of a Living thing as would be called into play during its contiuance as a growing Living thing. The presumption, therefore, is a fair one, that solutions which are favourable to the growth and development of certain organisms would also be favourable to the evolutional changes which more especially lead to the initiation of such Living things. Seeing, then, that the question of the occurrence or non-occurrence of such initiations is the very matter in dispute, it is certainly most imperative that no one engaged in investigations bearing on the subject should fail to appreciate this that these are possibilities whose probability ought to be assumed as equal. We may well be amazed, then, at the utter one-sidedness of M.

* Dec. 23, 1869. The weather being very cold and frosty. The mixture employed was another portion of the same solution as was used in *Experiment* 9.

* The reverse results, which may be produced by neutralising the acidity of a naturally acid fluid, will be exemplified further on.

† Taking it only for what it is worth, it is, at least, deserving of mention that no reason seems assignable for the presence of *Torulæ* in the one saline solution and not in the other. They were both equally exposed to the advent of "germs." It can scarcely be imagined that the *Torula* germs did obtain access to the both solutions, but that they perished in that which was faintly acid, for, as a matter of fact, *Torulæ* are much more frequently met with in acid solutions than in those which are alkaline.

Pasteur, when we find him completely ignoring one of these points of view, interpreting all his experiments by the light of a foregone conclusion, and looking upon the different solutions employed solely as fluids which are destructive or not destructive to hypothetical "germs" at a given temperature.

It should not be understood that I regard all acid solutions as having a low evolutional tendency. On the contrary, I believe I have helped to show in this paper that *some* acid solutions are most prone to undergo evolutional changes of a certain kind. These do not result in the production of Living things of a high type, but rather in an abundance of organisms of a comparatively low type. It seems to me, however, after careful observation and experiment, that a neutral or slightly alkaline solution to which a few drops of acid have been added is always found, after a given time, to contain a notably smaller number of organisms than an equal bulk of the unaltered solution. And conversely, having an acid solution whose productiveness is known, the number of organisms found in equal bulks under similar conditions, can almost always be notably increased in either one of them by the mere addition of a few drops of *liquor potassæ*, so as to render it neutral or slightly alkaline. This, as I previously pointed out, *may* be interpreted as an indication that alkalinity, or neutrality of the fluids, is more favourable than their acidity for the occurrence of evolutional changes. And thus the fact that organisms were never met with when an acid "eau de levûre sucrée" was used in repeating the experiments of Schwann, though they were met with, on the contrary, in other experiments where portions of this same fluid had been used which had been rendered slightly alkaline by the addition of chalk, might be explained without the aid of that supposition which alone seems to have occurred to M. Pasteur.

But, after reflection on this subject, it seemed to me quite within the range of probability, that the difference between acid and alkaline solutions in respect of the number of organisms which are to be found therein, when these have been simply exposed to ordinary atmospheric conditions, might be exaggerated after they had been exposed to the temperature at which water boils. It seemed quite possible that high temperatures might be more destructive to organic matter when this was contained in acid solutions than when it existed in alkaline solutions. Just as the acid seems to exercise a certain noxious influence even at ordinary temperatures, it may be conceived that this influence, whatever its nature, may be increased in intensity with the rise of temperature, and with the consequent greater facility for the display of chemical affinities. Hot acids will frequently dissolve metals which would remain unaffected by them at ordinary temperatures; and chemical affinities generally are notably exalted by an increased amount of heat. Just as the addition of an acid, therefore, to a previously neutral or slightly alkaline fluid containing organic matter in solution, appears to alter its character in some mysterious way, so may we assume that its action upon the unstable organic molecules goes on increasing in intensity as the fluid becomes hotter. So that, when two portions of a solution containing organic matter —the one neutral and the other acid—have been raised to a temperature of 100° C., whilst the organic matter of the one has been injured only by the mere action of heat; that of the other solution, which has been acidified, has not only had to submit to the deleterious influence of the high temperature, but also to the increased activity of the acid at this temperature. Thus the result would be that the amount of difference between the two solutions which existed before they had been heated, would be found more or less increased after they had been exposed to the high temperature, in direct proportion to the increase in intensity of the action of the acid produced by such high temperature. What we know concerning the precipitation of albumen in urine is quite in harmony with this view. When albumen is present, and the fluid has an alkaline reaction, mere boiling does not cause its precipitation, though, if the reaction had been acid,* the albumen present would have been precipitated, when, or even before, the fluid was raised to the boiling temperature. Or, the same result might have been brought about by the addition of a small quantity of acid to a portion of a neutral or alkaline albuminous specimen which had just been boiled without having brought about a precipitation of the albumen. Thus, the addition or presence of a small quantity of acid, in conjunction with an elevated temperature, is seen to be capable of producing results which cannot be produced by the mere elevated temperature alone. But the fact that an isomeric transformation of albumen can be brought about in this way—that albumen can be transformed so as to be no longer capable of remaining in solution—shows that a molecular change has been brought about by the influence of the acid working at high temperatures, which neither the acid nor the heat, working alone, are capable of effecting.

* Provided this was not due to the presence of a mere trace of nitric acid.

With the view of throwing further light on this subject, on March 27 of the present year I made the following experiments:—A tolerably strong infusion of white turnip was prepared and subsequently filtered.* This had a decidedly *acid* reaction. It was then divided into two portions, one of which was allowed to remain unaltered, whilst to the other a few drops of *liquor potassæ* were added, so as to give the fluid a very faintly alkaline reaction. This addition produced a slight alteration also in the naked eye appearance of the fluid; the faintly whitish opalesence which formerly existed disappeared, and was replaced by an equally faint brownish tinge. About an ounce of each of the two fluids was then placed separately in two small flasks. The fluids were not heated at all, but a piece of paper having been placed loosely in the neck of each so as to exclude dirt, they were exposed side by side to a temperature varying from 75° to 85° F. After twenty-four hours,† the unaltered acid infusion merely showed a more decided opalesence approaching to cloudiness; though that which had been rendered faintly alkaline, had a distinctly opaque whitish colour, and there was also a distinct pellicle covering more than one half of the surface of the fluid. In the three or four succeeding days the amount of opacity, of pellicle, and of deposit increased in both the fluids, though each of these continued to be more manifest in the alkaline than in the acid solution. After a week, however, the difference was scarcely appreciable, though on the whole, for about two weeks afterwards, the quantity of new matter seemed to be greater in the alkaline than in the acid solution.

But, on the same morning that these two portions of the acid and alkaline infusions had been set aside for observation, I had placed with them vessels containing two other specimens of the same fluids. These had been previously treated in the following manner: The acid fluid and the alkaline fluid, after they had been placed in their respective flasks, and the necks of these had been drawn out, were then boiled for ten minutes, and at the expiration of this time—whilst ebullition was still continuing—the drawn-out necks of the flasks were hermetically sealed in the blow-pipe flame. These vessels, therefore, were intended to show, by comparison with the other two, whether the difference produced by mere acidity or alkalinity of the solutions at low temperatures was or was not intensified by the action of heat. The flasks were all suspended in a group at the same time, and were, thenceforward, subjected to the same temperature. The results were as follows: After twenty-four hours the slightly alkaline fluid which had been boiled showed a slight though decided opalescence; it was, in fact, very similar in appearance to the acid solution which had not been boiled. The boiled acid solution was, however, as clear as when the flask was first suspended, and so it remained, apparently quite unaltered, after it had been suspended a week, though the boiled alkaline solution had by this time become decidedly opaque, and also showed some flocculent matter lying at the bottom of the vessel. And now‡, after they have been suspended more than three weeks, the acid solution still remains almost transparent, presenting only the faintest cloudiness, though with no pellicle or deposit at the bottom.§ The boiled alkaline fluid, however, presents a totally different appearance; it is whitish and quite opaque, there is a very thick pellicle covering part of its surface, and also some whitish sediment at the botton of the flask.

The difference which already exists between alkaline and acid solutions at ordinary temperatures is, then, seen to be most notably intensified after similar alkaline and acid solutions have been raised to a temperature of 100° C. And whilst these differences tend to substantiate the reality of the other mode of explanation (which I have suggested) of the discrepancies observed by M. Pasteur when he repeated Schwann's experiments with acid and with alkaline organic infusions respectively, they may also

* The turnip at this season of the year was however very poor and dry as compared with that which was employed in some of my earlier experiments (*Experiments* 4 to 9) during the winter months.

† During the whole of this time the heat only varied between the limits mentioned.

‡ April 19, 1870.

§ This solution was, therefore, much more backward in exhibiting signs of change than were the others which had been used in *Experiments* 4 to 8—a difference probably explicable by the poorer quality of the turnip used in this last experiment.

be considered to strengthen the probabilities in favour of my assumption that an acid fluid is less prone to undergo those molecular changes which lead to the evolution of Living things, than an otherwise similar fluid whose reaction is neutral or faintly alkaline. And yet this explanation was utterly ignored by M. Pasteur; he wrongly assumed that the before-mentioned discrepancies were explicable only in one way; and he moreover illogically attempted to set aside a rule to which he had previously assented, on the strength of evidence which was most ambiguous, and, therefore, inconclusive—in nature. M. Pasteur engages himself in a controversy concerning one of the most important questions in the whole range of biological science, and yet he assumes the attitude of a man who is so convinced beforehand of the error of those who are of the opposite opinion, that he will not abide by ordinary rules of fairness, he will not even, at first, assume the possibility of the truth of the opinions which are opposed to his own. Ambiguous evidence is explained as though it were not ambiguous; conclusions based upon good evidence are attempted to be set aside in favour of conclusions based upon evidence which is comparatively worthless; and, by such illogical methods, M. Pasteur proclaims that he has "mathematically demonstrated" the truth of his own views. Unfortunately for the cause of Truth, people have been so blinded by his skill and precision as a mere experimenter, that only too many have failed to discover his shortcomings as a reasoner.

But it will already have been perceived by the attentive reader, that it was not necessary for me—in my endeavour to establish as a Truth the great doctrine which M. Pasteur has striven to repudiate—to show the inconclusiveness of his reasonings on that branch of the subject to which I have just been alluding. I have striven rather to show in their true light the real nature of such modes of reasoning, which are I fear only too likely to be repeated by others. So long as people are unable readily to appreciate the worthlessness of arguments like these, they will never be likely to penetrate through the clouds of controversy which envelope this subject. Their mental vision will be blinded, and the truth will remain hidden from them. But, lured on by the success of reasonings such as these, others would have grown bolder still, and precisely as the exigencies of the case required, so would the standard of vital resistance to heat have been raised. What object can there be in laboriously ascertaining by direct experiment and observation at what temperature the lower kinds of organisms cease to live, if the information so obtained is to be studiously ignored just when it ought to be used as a kind of touchstone, or as a lamp to illumine phenomena whose explanation would otherwise be doubtful? It is a very easy process, certainly, first to start with the assumption that it is "impossible" for Living things to be evolved *de novo*, and then, every time that Living things are found under conditions where they ought not to occur (if the assumption were true, and if the generally received notions concerning vital resistance were correct), to assume that the very fact of their having been found under these conditions, of and by itself, shows that the previous notions concerning vital resistance were entirely wrong, and that the organisms which were formerly admitted to have been destroyed by a temperature of 100° C., must now be considered to be able to brave for four hours a temperature of 150° C., simply because they have been found in fluids which had been submitted to this temperature. The reasoning by which Truth is sought to be ascertained is, in fact, this:—No matter what the temperature to which the solutions and the hermetically sealed flasks have been exposed—be it even 500° C.—if Living organisms are subsequently found in the solutions, then they or their "germs" *must* have been able to resist the destructive influence of such a temperature, simply because Living things have been found, and because it is *assumed* that they cannot be evolved *de novo*. It is to be hoped that this is not the kind of reasoning which will find favour with those who are seeking for the advancement of Biological Science!

My principal objects in this paper have been to show:—

1. That there is a strong *a priori* probability in favour of the possibility of the occurrence of the heterogenous evolution of Living things, and that the most reliable scientific data which we possess do, in fact, fully entitle us to believe in this as a possibility.

2. That microscopical investigation, whilst it teaches us as much concerning the mode of origination of the lowest Organisms as it does concerning the mode of origin of Crystals, enables us to watch all the steps of various processes of heterogenous Evolution of slightly higher Organisms, such as may be seen taking place in a pellicle on a fluid containing organic matter in solution.

3. That the kinds of organisms which have been shown to be destroyed by a temperature of 100° C. may be obtained in organic fluids, either acid or alkaline, which, whilst enclosed within hermetically sealed and airless flasks, had been submitted not only to such a temperature but even to one varying between 146° and 153° C. for four hours.

4. That a new and direct evolution of organisable compounds may, in all probability,* be capable of arising, sometimes by isomeric transformation of the atomic constituents of a single saline substance such as tartrate of ammonia, and sometimes by a re-arrangement of certain of the atomic constituents belonging to two or more saline substances existing together in solution. It is not only supposed that this may occur, but that even Living things may subsequently be evolved therefrom, when the solutions have been exposed, as before, in airless and hermetically sealed flasks to a temperature of 146° to 153° C. for four hours.

On account of this *a priori* probability, and in the face of this evidence, I am, therefore, content, and as I think justified, in believing that Living things may and do arise *de novo*. Such a belief necessarily carries with it a rejection of M. Pasteur's Theory of Putrefaction, and of the so-called "Germ Theory of Disease."

H. CHARLTON BASTIAN

* It is not pretended that this is proved. The aid of the chemist and physicist must be much more extensively resorted to before such a point could be proved. I hope soon, however, to be able to bring forward additional evidence bearing upon this part of the subject.

WAR

THE dogs of war are again let loose, and in the two most highly civilised countries of Europe, where, a week ago, science, education, and commerce were in full sway, all the arts of peace are already neglected, and in prospect have gone back a quarter of a century. We can hardly yet realise that at the present moment railways are being torn up, lighthouses dismantled, lightships towed into harbour, and monuments of engineering skill, such as the bridge over the Rhine at Kiel, undermined, so that they may be destroyed at a moment's notice. But these, after all, are calamities of the second order; education is stopped; science schools are broken up; while we write both professor and pupil are forsaking the laboratory and the class-room, and the whole machinery of progress has come to a stand-still.

This journal, of course, has nothing to do with Politics: the function of Science is to unite the whole human family, whereas the function of Politics seems to be, both in the case of the human family and of each nation, to create parties and to emphasise them as much as possible, the object in each case being place for the partisans—whether that place be an income of a few thousands a year in one case or increased territory in the other. But although we cannot discuss politics, we may point out that as Science advances such policies will be overridden—that when Science and Education have taken their proper position—when the sword has given place to brain—when more of the best men of each nation take part in each nation's counsels, the dreadful thirst after blood will give way to something better; monarchs will see the folly of being surrounded merely with empty helmets and uniforms, or at all events if they do not, others will; and much will have been done when the pampering of armed men shall cease.

There is one point however in connection with the coming war which we cannot point out too strongly—one duty which England owes to herself, and which, if it be well done, may make her after all a gainer from the dreadful strife. We have already stated, and the statement is not an exaggeration, that the war will throw the countries engaged in it back a quarter of a century. Now, England at the present moment, be the cause what it may, is in many things a quarter of a century behind France and Prussia, notably in education of all kinds, and especially in scientific education.

The following extract from the Report of Mr. Samuelson's Committee on Scientific Education—a report which we believe has not even yet been taken into consideration by our Legislature—is so much to the point that we give it here:—

"Nearly every witness speaks of the extraordinarily rapid progress of Continental nations in manufactures, and attributes that rapidity, not to the model workshops which are met with in some foreign countries, and are but an indifferent substitute for our own great factories, and for those which are rising up in every part of the Continent; but, besides other causes, to the scientific training of the proprietors and managers in France, Switzerland, Belgium, and Germany, and to the elementary instruction which is universal amongst the working population of Germany and Switzerland. There can be no doubt, from the evidence of Mr. Mundella, of Prof. Fleeming Jenkin, of Mr. Kitson, and others, and from the numerous reports of competent observers, that the facilities for acquiring a knowledge of theoretical and applied science are incomparably greater on the Continent than in this country, and that such knowledge is based on an advanced state of secondary education.

"All the witnesses concur in desiring similar advantages of education for this country, and are satisfied that nothing more is required, and that nothing less will suffice, in order that we may retain the position which we now hold in the van of all industrial nations. All are of opinion that it is of incalculable importance economically that our manufacturers and managers should be thoroughly instructed in the principles of their arts.

"They are convinced that a knowledge of the principles of science on the part of those who occupy the higher industrial ranks, and the possession of elementary instruction by those who hold subordinate positions, would tend to promote industrial progress by stimulating improvement, preventing costly and unphilosophical attempts at impossible inventions, diminishing waste, and obviating in a great measure ignorant opposition to salutary changes.

"Whilst all the witnesses concurred in believing that the economical necessity for general and scientific education is not yet fully realised by the country, some of them consider it essential that the Government should interfere much more actively than it has done hitherto, to promote the establishment of scientific schools and colleges in our great industrial centres."

It is impossible that we can say anything stronger than this in favour of taking the fullest advantage of the opportunity of regaining our intellectual and therefore our commercial prestige.

If England is to prepare for war, the abnormal condition, so let it be; but surely, *a fortiori* she should *prepare for peace*, the normal one, as well. This has never struck her ministers, and the reason is not far to seek.

But this is not all; the same disregard for science, arising from the ignorance of science among our rulers, has probably placed us in another position of disadvantage. While France and Prussia have been organising elaborate systems of scientific training for their armies, a recent Commission has destroyed what little chance there was of our officers being scientifically educated at all. As there is little doubt that a scientific training for the young officer means large capabilities for combination and administration when that officer comes to command, we must not be surprised if the organisation of our army, if it is to do its work with the minimum of science, will, at some future time, again break down as effectually as it did in the Crimea, or that our troops will find themselves over-matched should the time ever come when they will be matched with a foe who knows how to profit to the utmost from scientific aids.

While, therefore, the Continent is being deluged with blood, let us *prepare for peace* as well as for war; let us prepare ourselves for victories in the arts, conquests over nature; let us, by means of a greater educational effort, more Science Schools, a truer idea of the mode in which a nation can really progress, fit ourselves to take our place among the nations when peace returns. Surely if there be statesmen among us, such a clear line of policy will not be overlooked.

Education and Science at the present moment are England's greatest needs.

HEIGHT AND WEIGHT

WITHIN the last few years public attention has been drawn to the question of what individuals weigh, by the facilities afforded for weighing by the construction of weighing-chairs. These chairs are not only to be seen at the Crystal Palace, where diminutive boys tout for custom, offering to tell your "correct weight," but they are also seen at the stations of the Metropolitan Railway and many other places. The practice, therefore, of getting weighed is obviously on the increase, and we want to utilise the knowledge thus gained by showing how it may be turned to most advantage. It will be easily seen that to know the weight of a person without reference to some other standard, such as height, would be of little advantage. But if by taking the height of a person we can say what he ought to weigh, then we have a means of ascertaining what persons ought or ought not to weigh. The difficulty on this subject has been to determine what a man of a certain height really ought to weigh. If this can be determined, then we can say whether a man of a certain height exceeds or falls short of the average weight of men of his stature.

One of the earliest efforts made to obtain anything like a fixed relation between height and weight was that of Dr. Boyd, who weighed a certain number of inmates in St. Marylebone Workhouse. He took the height and weight of 108 persons labouring under consumption, and found they measured 5ft. 7in., and weighed ninety pounds. He then measured and weighed 141 paupers who were not consumptive, and found that their average height was 5ft. 3in., and that they weighed 134lb. This subject attracted the attention of the late Dr. John Hutchinson, and he determined to take the height and weight of all classes of persons in the community. In this way he collected the height and weight of upwards of 5,000 persons. This list, however, included persons who exhibited themselves as giants and dwarfs, and other exceptional cases. He therefore reduced his instances to 2,650 persons, all of whom were men in the vigour and prime of life, and included sailors, firemen, policemen, soldiers, cricketers, draymen, gentlemen, paupers, and pugilists. This group of cases was intended to make one class as a set-off against another, so as to get a fair average. The following is the result of Dr. Hutchinson's observations :—

Height.	Weight.	Height.	Weight.
ft. in.	st. lb.	ft. in.	st. lb.
5 1	8 8	5 7	10 8
5 2	9 0	5 8	11 1
5 3	9 7	5 9	11 8
5 4	9 13	5 10	12 1
5 5	10 2	5 11	12 6
5 6	10 5	6 0	12 10

Of course the result of these investigations of Dr. Hutchinson can only be considered as approximative, and he himself thought that a larger number of observations would lead to a more perfect law. The fact is, his observations are quite sufficient to establish all that we need, and to show that amongst a certain set of healthy men his estimate of weight and height may be regarded as an approach to a healthy standard. It is only where considerable departures from the estimates given by Dr. Hutchinson take place that any particular case demands attention. If this table is examined, it will be seen that the increase in weight for every inch of height is a little more than five pounds. In fact, allowing for any error in observation, we may say that Dr. Hutchinson's table is reducible to the law that for every inch of stature beyond 5ft. 1in., or sixty-one inches, a healthy man increases five pounds for every inch in height. If this deduction be accepted, we may very much simplify Dr. Hutchinson's table, and say that as a rule, a man's weight increases at the rate of five pounds for every inch of height, and this rule holds good for all practical purposes. Starting then with a person 5ft. in height, who, according to the assumed law, should weigh 8st. 3lb., we obtain the following results :—

Height in inches.	Height in feet.	Weight in pounds.	Weight in stones.
in.	ft. in.	lb.	st. lb.
60	5 0	115	8 3
61	5 1	120	8 8
62	5 2	125	8 13
63	5 3	130	9 4
64	5 4	135	9 9
65	5 5	140	10 0
66	5 6	145	10 5
67	5 7	150	10 10
68	5 8	155	11 1
69	5 9	160	11 6
70	5 10	165	11 11
71	5 11	170	12 2
72	6 0	175	12 7
73	6 1	180	12 12
74	6 2	185	13 3
75	6 3	190	13 8
76	6 4	195	13 13

Although this law is approximately good for a certain number of cases, even above and below this table; it is practically found, and especially in the case of children and growing persons, that there is a wide difference of weight at heights below 5ft.

Attention may also be drawn here to the fact that there will constantly occur in the community instances of persons where either the muscular or bony systems are excessively developed, and who consequently weigh more or less than their height. Dr. T. K. Chambers, in his admirable essay on corpulence, published in 1859, calls especial attention to the researches of Mr. Brent on the assumed weights of the statues of antiquity. In order to get at this, Mr. Brent immersed in water accurate copies of these statues, and by ascertaining the quantity of water they displaced he calculated their weights. Dr. Chambers has taken the pains to reduce the absolute weights of these statues to assumed heights, and thus compared the heights and weights of these statues of antiquity with Dr. Hutchinson's modern man. Without giving the whole of the heights and weights, we present the series at the assumed height of 6ft. Thus :—

	Height.	Weight.
	in.	st. lb.
Bronze Tumbler .	60	11 4
Hutchinson's Man	60	12 10
Dying Gladiator. .	60	14 0
Theseus, Brit. Mus.	60	15 0
Hercules, ,, ,,	60	16 10
Farnese Hercules.	60	18 7

On this table Dr. Chambers remarks: "Of the statues here selected, the Bronze Tumbler may be taken as the type of extreme lightness and activity, the Dying Gladiator of robust strength. In Theseus and the smaller Hercules the sculptor's idea of a hero where the bodily strength must be equal to that of any possible man. The Farnese Hercules exhibits a development of muscle greater than is ever known to exist in the human species."

Dr. Chambers also gives the height and weight of certain celebrated prizefighters, the result of Mr. Brent's observations, which makes it very obvious that in certain cases the great weight depends on muscular and osseous development.

	Height.		Weight.	
	ft.	in.	st.	lb.
Perrins	6	2	17	0
Caunt	6	2	14	7
Spring	5	11	13	3
Jackson	5	11	14	0
Bendigo	5	9	12	0
Johnson	5	8	13	5
Slack	5	8	13	10
Mendoza	5	7	12	4

The conclusion we come to with regard to these weighings and measurings is that all ordinary departures from the average height and weight of the body deduced from Dr. Hutchinson's tables are due either to an increase or decrease of the fatty matter or of the adipose tissue in the body. Thus, taking the composition of a human body weighing 154lb. and measuring 5ft. 8in., it will be found that it contains 12lb. of fat.* It is then mainly due to the diminution or increase of this substance that human beings weigh more or less than the standard weights given in the above table. It will be therefore here worth while to inquire what is the use of fat in the system, and what indications are afforded by the height and weight of the human body for caution in diet and regimen.

The exact way in which fat is produced in the tissue of plants and animals is not known, but there is evidence to show that it is found very generally in the tissues of plants and especially in the seeds. Oil when used for commercial purposes is mostly obtained from the seeds of plants, as seen in castor oil, rape oil, linseed oil, cocoa-nut oil, palm oil, and a hundred others. As it is found in the seeds of plants, so it is found in the eggs of animals. The embryo of all animals is developed in contact with oil, of which we have a familiar instance in the yelk of the egg of birds. It appears also that the muscular and other tissues grow under the fostering influence of the adipose tissue.

Besides this primary influence on the growth of the body, fat subserves many other purposes. In the first place it seems to be a reserve of material for producing muscular force when needed. Animals grow fat in summer, but as the supply of this material becomes scanty in winter they lose their fat and get thin. Man himself gets fat in summer and grows thin in winter from the demand on this store for heating purposes. Hybernating animals go to their winter sleep sleek and fat, but wake up in the spring lean and meagre, from the loss of fat in maintaining the animal heat necessary for life. Fat is thus seen to be an essential of animal life. Where there is too little deposited for the purposes of life, then serious disease has already commenced or may set in; whilst on the other hand a redundancy of this deposit may seriously interfere with the functions necessary to life.

It is from this point of view that the value practically of a knowledge of the height and weight of individuals becomes apparent. When the weight of a person is much below his height, then it may be suspected that some disease has set in, which may go on to the destruction of life. One of the earliest symptoms of consumption, the most fatal disease of the civilised inhabitants of Europe, is a tendency to loss of weight. Long before any symptoms are present of tuberculous deposits in the lungs, this loss of weight is observable in persons afflicted with consumption. And at this stage a large amount of evidence renders it probable that the fatal advance of this disease may be prevented. Within the last thirty years a practice has been resorted to with great success of administering to persons losing weight and threatened with consumption, cod-liver oil, pancreatic emulsion, and fatty substances, as articles of food, for the purpose of preventing or arresting the tendency to loss of fat, which obviously results in the production of fatal disease. In fact, it may be stated generally, not without exceptions, that wherever the weight is much below the height, there the commencement of dangerous disease may be suspected, and precautions taken to prevent the loss of fat. That this treatment has been successful in really preventing disease, and loss of life as the consequence, is the conviction of a host of intelligent practitioners of medicine. At the same time, it should be remembered that it is not only necessary in these cases to administer cod-liver oil or pancreatic emulsion as medicines, but that the consumptive should have recourse to a fatty diet, and should eat butter, cream, cream-cheese, fat, and fatty articles of diet.

On the other hand, this knowledge of the true relations of height and weight presents us with individuals who weigh a great deal more than the standard presented by the above tables. In certain individuals, and, in fact, in particular families, there is a tendency to develope adipose tissue. However free from fat may be the food, what little it contains is arrested in the tissues of these individuals, and they become "fat;" that is, they weigh more than their height. The consequences of this fatness are very various. The fat may be so deposited all over the system as not to be an obvious obstruction to the functions of life; but every one can understand that, in the case of two men of equal stature, say 5ft. 8in., one having to carry eleven stone and the other twelve, the latter will be at a disadvantage. This arises from two causes. The heavier man carries, in the first place, a greater weight, and in the second place, his heart has to project into the tissues of the body a larger amount of blood in order to keep him alive. For every pound a man weighs above his height, his system is at a disadvantage, and he suffers in various ways. When fat is equally distributed about the body then no immediate disadvantage is felt. But when fat is accumulated in particular parts of the body, interfering with the functions of particular organs, then its evil influences become speedily apparent. The most accurate account of the effects of the accumulation of fat in the viscera of the chest, will be found in a pamph-

* See Guide to the Food Collection, South Kensington. Third Edition.

let by Mr. Banting, who, although not at all what we should call a fat man, nevertheless, so suffered from fat in the chest that he could not walk forwards downstairs, or stoop to buckle his shoe. There is no doubt that in his case there was a necessity for immediate relief, and he obtained it by abstaining from articles of food which supply fat to the system.

When persons weigh much above their height, it is obviously a matter of importance that they should as much as possible relieve the tax put upon their muscular and circulating system by diminishing their weight. Fortunately, this is not a very difficult thing to do, but it should be done with caution. "To Bant" with success requires caution. The immediate withdrawal of all fatty food, and the substances, such as starch and sugar, which produce fat, is frequently attended with dangerous results. Mr. Banting's diet, although so beneficial in his case, was not altogether a judicious one, and we have no doubt that many of our "stout" friends have found an early grave by their determination to reduce themselves to the standard of weight for their height. With regard to stout people, or those who weigh more than their height, it should be recollected that if they have suffered no inconvenience from their weight, it is better to leave well alone. There are few people living in the scientific circles of London who are not well acquainted with the portly forms and genial faces of well-known men from seventy to eighty years of age. It would be folly on the part of the men who have thus achieved the normal age of threescore years and ten to commence any system of artificial diet, when their natural instincts have guided them, in spite of their weight, to their present green old age.

When studied from a judicious point of view there is no doubt that an estimate of the height and weight of an individual ought to enter into every estimate of the possible chances of life. In medical practice it may become the deciding point of the treatment of disease; whilst in those estimates which Assurance offices are obliged to make of the prospective value of life, it is of the utmost importance. Whenever the weight is below the height there is a fair suspicion of scrofulous or tuberculous disease, which no Insurance office is justified in overlooking. Whilst, on the other hand, when the weight is greatly in excess of the height, there is a tendency to those sudden impairments of muscular and especially circulating powers, which may lead to premature and unexpected death. E. LANKESTER

FOSSIL MAMMALS OF NORTH AMERICA

The Extinct Mammalian Fauna of Dakota and Nebraska; together with a Synopsis of the Mammalian Remains of North America. By Dr. Leidy. With an Introduction on the Geology of the Tertiary Formations of Dakota and Nebraska; with a map. By Dr. Hayden. (Philadelphia, 1869. London: Trübner and Co.)

II.

IN the preceding article the Miocene portion of Dr. Leidy's great work has been reviewed. That part of it relating to the Pliocene and the Quaternary still remains for analysis. That we are able to classify the American Mammalia as the Miocene, Pliocene, and Quaternary, we owe to Dr. Leidy; and his definitions of the two former of these are amply supported by the results arrived at by the Geological Survey of the district, under the direction of Dr. Hayden. The Pliocene strata on the Niobrara River, and in the valleys of the Platte and Loup Fork Rivers, rest on the Miocene beds, which furnished the Mammalia treated of in the first essay. And thus there is evidence that the one series is of later age than the other. Palæontologically, also there is a most remarkable break. Not one species and only one or two genera, namely, Rhinoceros and Castor (Aceratherium ?), are common to the two. With this exception, all the Miocene Mammalia had disappeared during the time that intervened between the formation of the two lacustrine deposits in that region. This fact implies that the one formation is separated from the other by a shorter interval than their European analogues; for in the latter many genera, such as the Mastodon, Hipparion, Hyæna, Elephant, and others, pass from Miocene into Pliocene in such a way as to cause one group of life gradually to shade off into the other, and to render it sometimes impossible to define the last stage of the one from the first of the other.

In the American Pliocenes a Ruminant, the *Merycohyus*, possessed of a full complement of teeth, represented the family to which the Oreodon of the preceding epoch belonged. One species, *M. elegans*, was about the size of a sheep, while a second, *M. medius*, was rather larger. Since the latter is founded only on one upper and three lower molars, it is rather hard to follow Dr. Leidy when he defines the animal as being "one half larger in diameter than *M. elegans*, and intermediate in size between the lama and camel." From such a slender premiss, any exact estimate of the size of the animal must be worthless. The camel tribe were represented by three distinct genera. The Procamelus is distinguished from the camel by the presence of an additional premolar in the upper, and two in the lower jaw. One species, *P. robustus*, was about the size of the living camel. The Homocamelus is remarkable for its large canine, and for the isolated position of the first upper premolar; while the *Merychodus necatus* had molars without an accessory column between the lobes, as in the sheep. The deer is represented by one small species, *Cervus Warreni*, with antlers small and bifurcating, like those of the *C. trigonalis*, figured by M. Gervais from the French Pliocenes, and the *C. dicranoceros* from the Suffolk Crag, and the Miocene of Eppelsheim. One small bifurcating antler, or horncore, may possibly be the solitary evidence of the presence of the antelope in America, but it more probably belongs to a species of deer. In none of the living antelopes is the horncore prolonged into the branch of the horn. *Cosoryx furcatus* therefore cannot fairly be quoted in proof of the range of those herbivores as far as North America.

The Pliocene American Rhinoceros (Acerathere ?) *R. crassus*, belongs to the brachydont division, characteristic of the Pliocenes and Miocenes in Europe. The Mastodon, *M. mirificus*, was devoid of tusks in the lower jaw, and belonged to the tetralophodont section of Dr. Falconer. A species of elephant (*E. imperator* Leidy) was also living during the American Pliocenes. So far as the fragmentary condition of the molar will admit of decision, it belongs to the coarse-plaited variety *E. columbi* of Dr. Falconer. There were also at least three species of Hipparion, and two ancient forms of horse (*Merychippus* and *Protohippus*), which recall to mind the simplicity of pattern represented by equine milk molars. The true horse was represented by *Equus excelsus*; the beaver by the *Castor tortus*, which was half its size. There was also a porcupine (*Hystrix venustus*) which, strange to say, is more closely allied to the crested European than to the living American species. The wolves and foxes of the American Pliocenes are scarcely to be distinguished from those still living in the United States. One (*Canis sævus* Leidy) "is a near relative, if not progenitor, of the existing American wolf (*C. occidentalis*)." *C. temerarius* is intermediate between the prairie wolf and the red fox, while Dr. Leidy admits that the third (*C. vafer*) "may reasonably be supposed to belong to the existing swift fox." The fourth (*C. Haydeni*) probably belonged to a large variety of the western wolf. The larger felines are represented by the Pseudælurus (*Felis quadridentatus*), which was intermediate in size between the panther and the American lynx; and the bear-tribe by the *Leptarctus primus*, a creature allied to the coati.

The evidence afforded by this group of animals, of the physical geography of North America during Pliocene times, is extremely valuable. The absence of the Edentata and of the Rodents of South American type implies that North America at the time was insulated from the south by a barrier which could not be overcome by those animals. The absence of the opossums also points in the same direction. The Isthmus of Panama had not yet risen above the waves to sever the Atlantic from the Pacific Ocean, and to be a bridge for animals migrating from the one continent to the other. On the other hand, the Pliocene genera which dwelt in the basin of the Mississippi point indisputably to an influx of animal life from some other area. The deer, the mastodon, and the elephant, the hipparion, and the true horse, and among the carnivores the genus *Canis* and the Pseudælurus, are perhaps the most significant of the new forms which characterise the American Pliocene. From what region did they come? A glance at the Miocene and Pliocene Mammals of Europe affords a satisfactory answer to this question. All these genera sprang into being during the European Miocene, and with the exception of the last lived also in the succeeding period. It is therefore only reasonable to infer that they found their way into North America from the Euro-Asiatic area, and the fact that they are Miocene genera in Europe renders it possible that their migration began at that time. Whether this reasoning be accepted or not, the lapse of time required, not merely by one or by two genera, but by a group of herbivores with their accompanying carnivores, to fight their way from Europe or Asia into the Southern States—a region which was already occupied by the Oreodonts and other forms—must have been enormous, and probably sufficient to account for the difference between the American and European Pliocenes. If the migration be not admitted, then we must fall back on the now exploded hypothesis of different centres of creation, for there is no other mode of accounting for the presence of the same genera or species in now widely separated regions. It may therefore be inferred from the study of American Mammals, that North America was isolated from the great southern mainland, and that it was connected with Euro-Asia during the Pliocene, as well as during the preceding Miocene epoch.

The Quaternary group of Mammals, in Dr. Leidy's synopsis, points to a considerable geographical change having taken place in the interval that separates the epoch of their existence from the Pliocene. The strange extinct South America Edentates, the Megatherium, Megalonyx, and Mylodon spread over the Southern States, and testify that the barrier, which had confined them to their ancient home in South America, had been removed. In other words they poured northwards over the bridge offered by the Isthmus of Panamá, and occupied the valley of the lower Mississippi. They were accompanied also by extinct forms of the Chinchilla and Cavy. In this way the date of the elevation of Panama above the waves may be satisfactorily ascertained. The Northern extension, therefore, of the South American genera, which at the present time range as far as Mexico and occupy the province of "Austro-Columbia," dates from the Quaternary or Post-Pliocene epoch.

There was, however, no similar geographical change in the relation of North America to the old world. The bisons, horses, and elks, if not identical specifically, are merely varieties or representative species. The Mammoth is common to the whole of North America, and to the vast area in the old world north of a line drawn through the Altai mountains, the Caspian, and the Mediterranean Seas. The musk sheep, so widely spread through Europe in the Quaternary, ranged through Asia along with the Mammoth to the Arctic Ocean, and was found by Captain Beechy in the frozen loam on the American side of Bheerings Straits. In the basin of the Mississippi it is represented by a cognate species, *Ovibos bombifrons* (female), and *O. cavifrons* (male). That these remains really belong to one species of Ovibos, is rendered almost certain by the concurrent and independent testimony of Dr. Rütimeyer and myself. The Cave-lion of Europe was also represented by the *F. atrox* of Natchez. Many other cases might be quoted to show that in those days the connection by land between North America and Asia must have been maintained. It therefore follows, as one might have expected from the soundings in Bheerings Straits, that Northern Asia has been separated from North America in comparatively recent times.

There is one striking fact to be noted in the Post-Pliocene America fauna. Just as certain European Miocene genera appear in the American Pliocene, so two forms which in Europe died out in the Pliocene, the Mastodon and Hipparion, lived on in America into the Post-Pliocene age. It would almost seem as if America was the refuge of forms which had been driven from the old world. That the musk sheep of the Post-Pliocenes of Europe and Asia still lingers only in the high northern latitudes of North America, is a parallel case. These inferences are based on facts accumulated with very great care by Dr. Leidy. His work is an admirable attempt to grapple with most difficult problems; it would have been of far greater value had its author abstained from founding species and genera in some cases from very scanty materials, and in others on the slightest variations from the ideal type.

W. BOYD DAWKINS

OUR BOOK SHELF

OF the *Bulletin de la Société Impériale des Naturalistes de Moscow*, we have just received the first, second, and third parts for the year 1869. The greater part of the important papers in the second part are on Botanical subjects. They include a monographic revision, with tables of species, of the Heliotropes of the eastern Mediterranean region, in which seventy species are cited, and twenty-two of them described as new; a notice of the occurrence of the white Truffle (*Rhizopogon albus*) in the neighbourhood of Moscow; a note on *Empusa muscæ;* and a revision of the species of Characium found in the vicinity of Charkow. Colonel Motschoulsky continues his seemingly interminable "enumeration" of the new species of Coleoptera collected by him during his travels, leading us to wonder how any one man could have collected so many beetles, and, having got them, how he can write so much about them. This, however, is but a small instalment. Another entomological paper of more consequence is a monograph of the genus *Abacetus*, by Baron Chandoir; M. Solsky has a notice of some beetles from Eastern Russia, and M. E. Ballion another on two species of sawflies. The most interesting zoological paper is on the anatomy and development of *Pedicellina* (Sars), by M. B. Uljanin, illustrated with two plates. In this paper our countryman, Mr. Gosse, is absurdly quoted as "Goosc." The remaining papers are by Dr. Ferd. Müller on the determination of the magnetic inclination, and by M. R. Hermann on the composition of Fergusonite. The last part consists of a series of *éloges* on Alexander Von Humboldt, read at a centenary celebration of the great German philosopher. These papers, by different authors, treat of Humboldt from various points of views: as a man and as a naturalist; in his relations to Russia; as an investigator in the domain of electro-physiology; as a botanist; as an investigator of physical geography and climatology. As they are all in Russian we fear these memoirs will find few readers in this country. A German translation of the first of these will, however, be found in the first part of the *Bulletin*, which includes a variety of papers on Natural History subjects. An important geological paper is one by Prof. Trautschold, on secular elevations and sinkings of the earth's surface. Dr. D. Zernoff's memoir on the olfactory organs in the Cephalopoda, which is illustrated with two plates, is a valuable contribution to the anatomy of the Mollusca. In an important memoir, also accompanied by two plates, M. J. Borsenkow describes the developmental history of the ovary and egg in the common fowl. For the botanist we have a continuation of M. L. Gruner's catalogue of plants collected on the Dnieper and the lower part of the Kouka; and a notice, by M. Alexander Becker, of Sarepta, of a journey to Debent, which also, as usual, includes entomological notices. For the entomologist finally we have a catalogue of the Coleoptera of the vicinity of Jaroslaw, by M. von Bell; remarks upon some species as cited in Harold's great catalogue of Beetles, by M. E. Ballion; and, from the inexhaustible Motschulsky, a further instalment of descriptions of new species of Coleoptera.

Für Baum und Wald. Eine Schutzschrift an Fachmänner und Laien gerichtet. Von Dr. M. J. Schleiden. (Leipzig: Engelmann. London: Williams and Norgate.)

A TREATISE on arboriculture, in which, mingled with some extravagant sentimentalism, are many useful hints as to the growth of trees and forests. There can be no doubt that within the last 2,000 years a great amelioration has taken place in the climate of Central and Northern Europe. Varro speaks of the climate of the south of France as unfavourable to the growth of the vine or olive. Virgil describes the Crimea as subject to the rigours of an eight-months' winter; Diodorus Siculus narrates how whole armies crossed the frozen Rhine, Rhone, and Danube; and there is unanimity of testimony among other writers to the same effect. Dr. Schleiden attributes this change in the climate, to a great extent, to the destruction of forests when the country became more thickly peopled, combined, no doubt, with improved drainage. He points out, however, that disforesting may be carried too far, until it becomes positively injurious instead of beneficial. The judicious mean he believes to have been arrived at in England and Ireland, while in some parts of Continental Europe, especially Switzerland and the Tyrol, the almost entire destruction of the timber has caused a diminution of the rainfall to an extent very prejudicial to the crops. Another result in mountainous countries has been the constant accumulation of rain-clouds around the mountain-peaks, and consequent destructive floods and devastating avalanches. In confirmation of Dr. Schleiden's views, it may be stated that in some parts of India the drought has been so severe for several successive years since the destruction of the forests, that the Government has ordered the planting of an enormous number of trees.

Twelve-wired Bird of Paradise

IT may be interesting to many of your readers to know that a specimen of the rare and beautiful twelve-wired Paradise Bird (*Seleucides alba*) is now alive in the Royal Zoological Gardens at Florence. Signor G. E. Cerruti, who has recently returned from an official tour in the Moluccas and New Guinea, writes me that he obtained it from the Rajah of Salwatty, and that although very wild at first, it soon became tame and quiet; and that he had very little trouble in bringing it home. Here is another proof that these wonderful birds can be brought to Europe without difficulty, and once here, with proper care and ample space, there is little doubt they would be long-lived.

ALFRED R. WALLACE

Spontaneous Generation

DR. H. C. BASTIAN, who has recently called attention to the nature of the evidence before scientific men in favour of the theory of so-called spontaneous generation, has supplemented it by fresh experiments of his own. The dilemma in which the opponents of this doctrine are now placed is that they must either admit it, or else allow that a temperature of 150° C. maintained for four hours, and applied by means of liquid, is incapable of killing the germs of infusoria. Many, doubtless, of these opponents will courageously mount this horn of the dilemma, and make the requisite enlargement of their ideas on the subject of vital resistance to change. There are, however, other difficulties in the way. For instance, great difficulties are involved in the assumption that the atmosphere constitutes a storehouse of germs of all kinds ready to burst out into life on the occurrence of suitable conditions.

However small these germs may be, still they must weigh something. And there must be very many of them, seeing that there must be an immense number of kinds of germs, if a volume of air is to supply to any given infusion precisely the right kinds of germs suitable to the conditions provided by the infusion.

Now chemists are in possession of data showing that the possible amount of organic nitrogenous matter in common clear water and common good air is remarkably small—so small, indeed, that the question may fairly be asked—Is it large enough to admit of the requisite number of germs, the existence of which the vitalists assume in water and air?

By the employment of our ammonia method, Chapman, Smith, and myself have shown that the organic ammonia from a kilogramme of good filtered water often falls as low as 0·05 milligramme, and Dr. Angus Smith has shown that a kilogramme of good air sometimes contains as little as 0·085 milligramme of organic ammonia.

A gramme of air—that is about 700 cubic centimetres—contains only 0·00085 milligramme of organic ammonia. Expressing the organic ammonia in its equivalent of dry albumen we have in 700 cubic centimetres of air 0·00085 milligramme of dry albumen. Translated into volume this 0·00085 milligramme of dry albumen will fall short of a cube, the face of which is $\frac{1}{10}$th millimetre in diameter.

Expressed in English measures, the result is, that rather more than one pint of average atmospheric air does not contain so much organic nitrogenous matter as corresponds to a cube of dry albumen of the $\frac{1}{250}$th part of an inch in diameter.

Now is this quantity adequate to admit of the existence of the immense multitudes of germs, the existence of which in atmospheric air is assumed by the vitalists?

J. ALFRED WANKLYN

Colour of the Sky

WITH reference to Mr. Brett's observations on the colour of sea and sky, I have one or two remarks to offer which I think may be of interest. Smokers have all noticed that the smoke from the end of a pipe or cigar is bluer than that which they puff from the mouth, and many may have wondered, as I did for a long time, what the reason of this could be. The contrast may be well seen on a bright sunny day. This is, in fact, the simplest form of the experiment of the condensation of vapours causing them to pass through a fine blue to a white condition, which Professor Tyndall exhibited about two years ago, and which he employed to explain the blue colour of the sky, and the remarkable polarisation of its light. The finer state of division in the freshly-formed smoke gives it its bright blue colour, as does the finely divided aqueous vapour give to the blue sky; the smoke which has passed through the pipe-stem and mouth has become more condensed, and consequently gives a whiter cloud.

The colour of water is, it appears, to a great degree dependent on the same cause as that of the sky. The investigations which Mr. Brett asks for have been already commenced. M. Soret, of Geneva, soon after Professor Tyndall's researches on the cause of the blueness of the sky were published, made similar researches on the waters of the lake of Geneva, and found that the light from the water, when blue, was polarised as the light from the sky, and, so far, there was the probability of the cause of the colour being similar in the two cases. (See *Comptes Rendus* (Paris), April, 1869.) That particles in a fine state of division are the cause of the blueness of water as well as of sky is also made evident from a comparison of the waters of different lakes, seas, and rivers. There are two popular theories as to the cause of the colour of masses of water, which have very deep root, and yet must, it seems, be abandoned. One is that seas or lakes are blue by reflecting the blue sky. On this ground I have heard Mr. Brett's picture in the Academy this year of a deep blue sea, severely criticised, because the sky, which he has painted with it, is not correspondingly blue, and could not furnish the sea's tint by reflection. Mr. Brett is, however, quite right in his fact, as many people know well enough; and the criticism was misplaced, if the blue colour of a mass of water is dependent on the reflection of light from within water containing finely-divided particles—not from the surface only—as explained above. The second popular theory which seems to be ill-founded is that the green colour of lakes, rivers, and seas is due to plants growing on the bottoms and giving their colour by reflection. The green colour is produced in the same way as the blue in all probability, and may be due to a yellowness of the water in some cases, but it is less easily accounted for than the blue colour. M. Sainte-Claire Deville is quoted by M. Soret as stating that waters which give a white residue on evaporation are *blue*, whilst those which give a yellow residue are *green*. Reflection of the colour of the sky, and of the plant colour from the bottom, does no doubt produce colour of water in some cases, but it is only in shallow pools that the latter can have any effect, or through perfectly smooth surfaces that the former can be effective. Some cases of water-coloration which I have noted will be not out of place here:—1. Intensely blue on a bright day, with pale sky and large cumulous clouds, was the colour of water in reservoirs twenty feet deep at Plumstead, depositing chalk (by means of which the water is softened according to a patent process). 2. Intensely blue (the bluest here noted)—Mediterranean at Marseilles. 3. Bright blue—Lake of Geneva. 4. Darker blue, tending to Indigo—sea near Guernsey; also the Laacher See, in the Eifel. 5. Pale blue—sea near chalk cliffs, being at a little distance from the coast green or greyish. 6. Pale blue or greyish blue—the Rhone, the Mosel, glacier streams, &c. 7. Green—the Rhine, the Scheldt (very markedly so at Antwerp, as testified in Belgian pictures), the Seine, Thames Estuary, &c. 8. Intense green—in patches on the Lake of Geneva; in the evening, when the sun was just below the mountains, more frequently on the Lakes of Thun and Lucerne. 9. Bright green—the sea, on a windy day, with bright sun, off the Isle of Man. 10. The sea round the coral reefs of Florida is said to be intensely green; when away from the coast it is deep blue. 11. On a heavy, clouded day, with rain, gleams of sunshine out at sea give patches of green colour and reddish brown. 12. Water standing in an old copper mine at Killarney was intensely green, whilst the water in the lake at the side was black in the mass. 13. Red colour is produced in some seas by algæ, in others and in some rivers by the breaking up of soil coloured red by iron. 14. Opaque green colour is produced in ponds (Serpentine and ornamental waters) by unicellular organisms, which sometimes swarm in these waters. They may similarly become red. Perhaps the most remarkable instance of blue colour, due to the optical properties of water, is the blue grotto of Caprera, where, at any rate, the reflection of the sky is eliminated. A similar phenomenon is the glorious blue and green of the glacier fissures.

Leaving the question of surface reflection aside, which can only come into play in the case of road-side pools and such mirror-like waters, and also leaving aside the appearance of vegetation in clear shallow streams and ponds, it seems that at the present time we may ascribe the blue colour of masses of water to a peculiar reflection of the light from within the water, accompanied with polarisation, and depending on suspended particles. Blackish, brownish, and yellow colour is due to vegetable matter in solution; reddish brown to iron, sometimes; green, sometimes, to copper or algæ, but the green commonly seen on seas, lakes, and rivers, like that of glacier-fissures, probably admits of a similar explanation to that of the blue. I trust some physicist may be induced to enter into the subject in these pages. Has not the production of a series of tints at sunset an origin which may tend to explain the various tints of blue and green waters? I find that Mr. Sorby in the *Philosophical Magazine*, November, 1867, ascribed the blue colour of the sky and the successive yellow orange and red tints of the setting sun to the absorption of the red rays more than the blue, by the fine aqueous vapour of the higher regions of the atmosphere, and of the blue rays more than the red by the coarser vapours near the earth's surface—as *e.g.* a fog.

The foregoing notes may suggest to others similar observations of greater importance, which it would be interesting to collect. It would be very satisfactory, and of interest to many readers, if some one who could speak with authority on the physics of light, would discuss these phenomena, however suggestively, in your pages.

Poisonous Fishes

IN answer to your correspondent M.D.'s second question in your issue of June 30th, I beg leave to refer him to Dr. Günther's article in this Society's "Proceedings," on a Poison Organ in a genus of Batrachoid Fishes. (P. Z. S., 1864, p. 155.)

Fall of an Aerolite, 1628

YOUR correspondent T. W. Webb may be glad to know that a graphic account of the Aerolite he refers to (NATURE, July 14) as having fallen in Berkshire in 1628, will be found in Vol. II. of Chambers' Papers for the People, published 1850, in an article entitled "Memorabilia of the 17th Century," p. 10. This article also contains many other very extraordinary and well-described accounts of earthquakes, floods, mirages, and various startling atmospheric phenomena which occurred during the 17th century. Amongst the latter the accounts of parhelia, or mock suns, and haloes, and the falls of two or three aerolites, are worth noticing.

Unfortunately, throughout the article the sources whence the various notices have been taken is uniformly omitted.

Alderley Edge, Manchester, July 17 J. P. EARWAKER

Are Jupiter's Cloud-belts due to Solar Heat?

A CIRCUMSTANCE which, so far as I know, has not yet been noticed, seems to me to afford very strong evidence in favour of my theory that the cloud-belts of Jupiter are caused by heat existing in the planet itself. If the cloud-belts were caused by solar heat, they should exhibit a characteristic corresponding to what is observed in the case of the earth's equatorial cloud-zone. "At the equator," Kämtz remarks, "the sun nearly always rises in a clear sky; towards mid-day the heavens are clouded; towards evening the clouds disperse." Now it follows that to an observer regarding the earth as we see Jupiter, there would appear at all times only a fragment of an equatorial belt, near the middle of the disc. But the belts of Jupiter present no such fragmentary appearance; there is a change in their aspect close by the edge of the disc, but the change is one obviously arising from the foreshortening.

Another circumstance also is worth noting. If the cloud-belts of the outer planets were sun-raised, the great tropical belt of Saturn ought to follow the sun as the tropical calm zone of the earth does. The fact that the Saturnian belt remains persistently equatorial is very significant. RICHD. A. PROCTOR

The Rotundity of the Earth

IN your number for July 14th, after publishing an *ex parte* statement, you ask, "Will nothing stop Parallax's mouth?" I hope you will allow me to say, in your next issue, that only one thing can operate in doing so! That one thing is a practical experiment fairly conducted, honestly reported, and logically applied. Your readers will notice that although my signature (Parallax) is appended to the "copy of agreement," it does not appear in the "copy of certificate," and it is proper they should know the reason. It had been agreed that the flags should be fixed in my presence, and that the spirit-level employed should be in good working order and to my satisfaction in every respect. On arriving at the "scene of operations" at the appointed time, I found that the flags had been fixed, and that the spirit-level had been adjusted for some time before my arrival. I immediately protested, and demanded that I and the friends with me should go and measure the altitude of each flag, but an obstinate resistance was offered to this, and also to any interference with the adjustment of the "level." I therefore at once declined to be longer present, and returned to Norwich, where the whole matter was exposed at a public meeting. Notwithstanding the manifest injustice of the attempt, and my refusal to have anything to do with it the moment I discovered its unfairness, these wise and clever and very just Newtonians would have the world believe that they had once and for ever settled the question of the earth's true form and magnitude. Such tricks are unworthy of the cause, and the men who can condescend to deal in them can do no real service to the school to which they belong.

I beg to give the friends of the Newtonian system the following simple challenge: To select six miles of still water, place a boat at one end, with a flag say six feet above the surface of the water. Now, at the other end, let a good telescope be fixed at an elevation of eighteen inches; I affirm that the boat and its flag *will be distinctly visible;* whereas, if the earth is a globe of 8,000 miles diameter, the top of the flag would be more than seven feet below the intervening arc of water. This is my challenge, and let the Newtonians decide that it shall be accepted; saying with me, "let us stand or fall by the result!"

1, Hawley Villas, Chalk Farm Road, PARALLAX
London, July 18

[We print "Parallax's" letter, but we warn everybody against accepting his challenge. Mr. Wallace's treatment at the hands of these gentry shows us what to expect. Let "Parallax" take a good telescope and a return ticket to some seaside place and watch the ships travelling to and fro over the horizon. We offer him space in NATURE to detail his observations, and to explain them, if he can, on any other theory than the received one.—ED.]

Eclipse of the Moon

THE eclipse of Tuesday evening (July 12) exhibited some interesting variations in tint and degree of illumination in different parts of the shadow. There seems to have been a dark spot, perhaps half the moon's diameter, about the centre of the umbra, nearly, if not quite, free from refracted light; outside this a ruddy zone; and beyond this again, to the edge of the shadow, a region strongly illuminated, comparatively speaking, with yellowish pink, as it appeared when projected upon the entering, or yellowish green upon the emerging moon. It is true that just after the commencement, and some little time before the end of the eclipse, the part just within the shadow appeared darker than the eclipsed limb; but this, I think, must have been an optical effect caused by the overpowering light of the uneclipsed portion.

When, however, about two-thirds or three-quarters of the moon's surface was covered, both before and after totality, the illumination of the umbra near its boundary was very conspicuous. The "seas" reflected less light than the other portions, and the regions along the south limb, and between the north limb and Mare Imbrium, were specially bright. These gave almost the effect of the illuminated cusps of the moon being distorted, and prolonged into the shadow. When the eclipse became total, the eastern hemisphere, about the region of Oceanus Procellarnus, was covered by a dark shade, so dark that the extreme eastern limb was scarcely if at all visible. A short time after totality the moon was quite hidden by clouds, and remained so, excepting occasional momentary glimpses, during which nothing could be seen, excepting that she was visible as a dull, pinkish light, till just before the end of the total phase, when the clouds broke away from her neighbourhood in a marvellously dramatic way. The emerging was wonderfully beautiful; first a strong, greenish light appeared along the eastern limb; this changed to silvery; then bright, full yellow. The eclipsed part was moderately bright, shining with a reddish light, excepting a deeper shade over the western hemisphere. In fact, the appearance was exactly analogous to that at the commencement of totality. I regretted extremely that I had not the opportunity of watching whether the dark spot really traversed the disc from side to side, but I have little doubt that at the time of central eclipse the moon presented a well-marked annular phase.

As the gathering of clouds, and their sudden dispersion at the end of the total phase, seems a striking instance of the supposed influence of moonlight in dissipating vapour, it is perhaps well to mention that after the end of the eclipse, clouds appeared to be again gathering round the moon.

The telescope I used was a $3\frac{1}{2}$-inch refractor, armed with a power of 35. GEO. C. THOMPSON

Cardiff, July 17

Wave-lengths of Complementary Colours

IN applying Mr. Maxwell's observations to the verification of a hypothesis (see NATURE for July 7), Mr. Murphy identifies complementary colours by their *names*, overlooking the fact that the observations themselves afford pretty accurate determinations of several pairs. Separate results are given for two observers in Tables VI. and IX. of the memoir formerly cited by Mr. Murphy (NATURE, April 28), and are laid down graphically in figures 4 and 5. From the latter form of the data, as the more convenient, though no doubt the less accurate, the following formula was obtained by interpolation, for the relation between complementary wave-lengths :—

$$(\lambda - L)(L' - \lambda') = M^2;$$

where λ is a wave-length between 2350 and 2100 (in Fraunhofer's measure); λ' is its complementary between 1820 and 1700; and L, L′, M are quantities differing for different eyes, and having the values

2076	1842	77·9	for observer "K;"
2132·5	1859·4	51·2	for observer "J."

Mr. Murphy's complementaries are not in general really complementary for either observer. Independently of this, Mr. Murphy's probable error is about ·53, that is, over one in 100: the probable error of the formula is certainly under one in 500, between the limits stated. C. J. MONRO

THE APPLICATION OF PHOTOGRAPHY TO MILITARY PURPOSES

MODERN warfare may in many respects be considered as so many applications of science. Not only is war *matériel* designed and manufactured nowadays upon the most approved data, and according to theories worked out with mathematical accuracy, but a large section of our soldiers are educated in such a manner as fully to appreciate the value of their resources, and so to overcome difficulties which years ago would have been regarded as impossibilities. No instance demonstrates this more satisfactorily than the recent Abyssinian expedition, which, whatever may be said of it as a campaign, cannot but be regarded as one of the most wonderful feats of engineering accomplished in modern times. The nearer warfare approaches perfection, the more decisive, and therefore less cruel it necessarily becomes, as witness the brief duration of the wars of late years on the Continent; and for this reason the improvements in warfare effected by science cannot by any means be regarded as a misapplication of knowledge.

Our present remarks bear reference to the applications made of a very modest branch of science, if science, indeed, it can be called, our object being to demonstrate the many uses made by the War Department of Photography. In the special application of this art-science to military matters, our government is certainly in advance of others, if we except, perhaps, that of France. No less than three establishments have been organised in connection with the army in which photography is extensively practised, the most important of them being the General Establishment at Woolwich; but besides these, there are again many Royal Engineer Stations, both at home and abroad, which are furnished with photographic requisites and employ the camera for divers purposes. At Chatham, the photographic establishment assumes the character of a school of instruction, at Southampton it forms an adjunct to the Ordnance Survey Office, while at Woolwich, of which department we desire more particularly to speak, the duties performed by aid of the camera are as various as they are numerous. For registering patterns, recording experimental results, imparting military instruction, and for other purposes too multifarious to enumerate, photography is extensively used, the faithful accuracy of sun pictures, as likewise the facility with which they are produced, causing the art to be eagerly employed in any way where it can be made available.

As an example of the value of photography in instruction, we would cite an interesting series of pictures taken to illustrate ordnance drill. This series comprises upwards of one hundred views, and demonstrates the practical working of the various kinds of guns, mortars, rockets, &c., in the service. One picture, for instance, will illustrate the command "Prepare for action"; a gun will be shown surrounded by a group of artillerymen in the positions they have been instructed to occupy on the issue of that order, each man having his respective number attached to his cap as a distinguishing mark. The next illustration in the series is probably that of "Load," and the next again "Fire," both of which will represent the change in position of the men, as one operation succeeds another, and the various duties performed in turn by each gunner or number, for it must be remembered that in gun-drill every man is told off to a particular number and entrusted with a separate and distinct duty. Thus, on the promulgation of any new system of drill, or of any modification in the method of working, it is merely necessary for the military authorities to forward pictures of this kind to the different instructors, who cannot fail at once thoroughly to understand the new exercise; and even the rawest recruit who had assigned to him a certain number at a gun would see at a glance the exact position he is to occupy by a reference to the photographs.

Another not less striking instance of the importance of photography in this connection may be given. At the outset of the Abyssinian campaign it will be remembered that several thousands of packsaddles were required for transporting war *matériel* into the interior. These packsaddles were made in and sent direct from England to Annesley Bay, so that the troops coming from Bombay knew nothing of their construction, nor of the method in which they were to be packed. This ignorance in the hurry of affairs would have been of serious consequence (for a military packsaddle of the present pattern is a somewhat complicated contrivance) had not the authorities at home been fully alive to the subject and foreseen the threatening difficulty. A mule at Woolwich was harnessed and packed, after some experience had been acquired in the matter, in the most suitable and approved manner, and the animal then carefully depicted by the aid of the camera; the disposal of the harness and trappings and the correct way in which the packages were to be carried, were thus clearly shown in a photograph, numerous copies of which were immediately sent out to Annesley Bay and distributed among the officers of the Quarter-Master-General's department.

In recording experimental results photography again fulfils a duty which could not be discharged so rapidly and impartially by any other means. The stout iron-cased shields and armoured targets built up of metal plates of different thicknesses, and then fired at with shot and shell of all descriptions, are carefully photographed after each decisive experiment, and a record of indisputable accuracy thus obtained. With a picture before us of a target, constructed to represent the side of an armour-plated vessel which has been experimented on, we can at once form an accurate estimate of the impressions made upon the iron wall by shot of different calibres, while rear and side views of the structure will show plainly the amount of damage which the backing or skin of the shield has suffered. As may be imagined these prints form important illustrations to the written reports made from time to time to the War Office authorities.

The photographing of newly adopted government patterns, whether in the shape of guns, carriages, waggons, mantelets, tents, &c., is also an important section of the work undertaken at Woolwich, as likewise that of producing pictures relating to army equipment, such, for instance, as demonstrate the setting up of cooking apparatus, disposal of ambulances, refitting of ordnance in the field, &c. There is, moreover, the pursuit of photo-lithography to be mentioned, by means of which designs and sketches are copied and transferred to stone for printing off in the ordinary manner.

The subject of working photography in the field is a matter to which much attention has been given at the general establishment, for it will be readily conceived that the simplest and most effective methods of working, as likewise the different uses to which the camera may be put during warfare are questions for very serious study.

The photographic copies, many thousands of which are annually produced and distributed over all parts of Her Majesty's dominions, are not now printed upon silver paper in the ordinary way, but by the so-called carbon or autotype process, a method which produces prints of an absolutely permanent character. Ordinary silver prints are always liable to become faded and stained after the lapse of a few years, owing to the presence in the paper itself, or in the atmosphere with which it comes into contact, of sulphur compounds which attack the metallic silver composing the image. In the carbon pictures, however, no silver at all is present, the composition of the image being a mineral pigment in combination with an insoluble chromium.

Our description of the General Photographic Establishment at Woolwich has been very brief indeed, but enough has been said to show to what an important extent the art is employed in connection with the War Office; the department which we have described is a branch of the chemical establishment of the War department, which was first organised, in 1854, by Mr. Abel, and has gradually become intimately and indispensably connected with every branch of the military service.

THE PHYSIOLOGY OF DIGESTION

I. MASTICATION

I PROPOSE in this and the following papers to give an account of the physiology of digestion, or, in other words, to describe the operations to which food is submitted, and the alterations it undergoes, before it is absorbed into the system and becomes adapted to the nourishment of the body.

With this end in view, it will be expedient to divide the alimentary or digestive tract into a series of sections, each comprising a portion in which certain definite and, in general, well-ascertained processes are effected. The first of these is clearly the mouth, where the food, provided it be not already of a fluid nature, is ground to a pulp and mingled with saliva, or, in other words, where it undergoes mastication and insalivation.

In order to prevent the ingestion of substances that, from their temperature, hardness, acridity, putrefaction, or other chemical or physical properties, are inappropriate as articles of food, the mouth, or vestibule of the alimentary canal, is guarded by three sentinels that, were due attention paid to the impressions derived from them, would rarely be found to mislead: *Touch*, possessed to an exquisite degree by the ruddy lips and tongue; *Taste*, possessed by the tongue and palate; and *Smell*, which, though comparatively neglected by man, is constantly

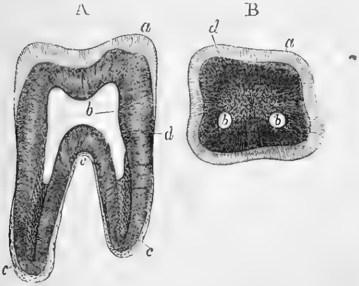

Fig. 1.—A, vertical; B, horizontal section of a bicuspid tooth; *a*, enamel of the crown; *b*, pulp cavity; *c*, cement of the fangs; *d*, dentine; magnified three diameters.

employed by animals as a means of discriminating suitable from unsuitable substances.

The act of mastication is designed to comminute the food, and thus to present a larger surface to the action of the several digestive fluids, saliva, gastric and intestinal juices, &c., as well as to render it more readily capable of incorporation with them. It is more important that it should be thoroughly performed in the case of vegetable than of animal food, since the latter is usually of a softer and more succulent nature, besides being already analogous in composition to the body; whilst the nutritive material contained in the former is enclosed in firm cell-walls that are slowly dissolved in the act of digestion, and requires the action of the several fluids to be long continued before it is fitted for nutrition; and it is accordingly found that the means for effecting such comminution is far more complete in the vegetable than in the animal feeders. In a teleological point of view it is interesting to notice that in the infant living on milk, which does not require mastication, no teeth exist till the fourth or fifth month.

Mastication is accomplished by the movements of the jaws, the margins of which are very generally armed with teeth. Amongst Mammalia the teeth are only absent in the whalebone whales, the anteater, manis, and echidna—many rows of small, sharp, hard, epidermal spines situated on the palate and base of the tongue, however, supplying their place in the last-named animal, whilst the two former may be said to live on animal food that is already, in proportion to the bulk of their bodies, extremely comminuted. Teeth are indeed absent in the whole group of Birds, and in the Chelonia, doubtless in the former case on account of their weight, which would interfere with flight, but their place is supplied in both by the cutting beak and in the latter also by the powerful gizzard. They are absent in the toad amongst Amphibia, and in the sturgeon, paddlefish, pipefishes, ammocete and amphioxus amongst Fishes, but are elsewhere constantly found amongst the Vertebrata; they are very frequent also amongst the Invertebrata, though many live by sucking the juices of the animals on which they subsist.

In regard to the teeth of man, it need only here be mentioned that they are twenty in number in the child, and thirty-two in the adult; that the six front ones, namely, the four incisors and two canines in each jaw, are chiefly employed for cutting and tearing the food; and the remaining back teeth, including the four premolars and the six molars, for pounding and bruising it. The teeth are the hardest parts of the skeleton. Four parts may be distinguished in them—(1) the pulp, which, occupying a cavity (*b*) in their centre, is extremely small in quantity, and contains an artery vein and nerve; (2) the dentine (*d*), which forms the greater portion of the tooth and confers upon it its general configuration; (3) the enamel (*a*), which caps the

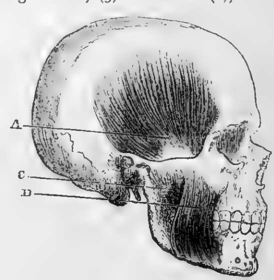

FIG. 2.—View of the external muscles of mastication. A, temporal muscle; D, superficial; and C, deep portion of the masseter muscle.

free or exposed surface of the tooth, or that portion which projects beyond the gum; and (4) the cementum (*c*), which invests the fang.

The Dentine (*d*) is composed of a series of tubes traversing a homogeneous matrix, and extending from the pulp cavity to the outer limit of the dentine. The course of these tubes is undulatory, and they give off numerous branches as they pass outwards. It is difficult to trace their minutest ramifications even with high powers of the microscope. Their interior is occupied by delicate solid threads called dentinal fibres, which, however, it has recently been shown by Neumann are not in immediate contact with the matrix, but are separated from it by a resisting membrane or dentinal sheath. The presence of these fibres accounts for the sensitiveness which it is well known the dentine when exposed possesses, whilst there can be no doubt they are subservient to the slow processes of nutrition which are continuously taking place in even the most superficial parts of these hard organs.

The Enamel (*a*) is composed of a series of six-sided, solid prisms, which contain scarcely more than 2 per cent. of organic matter, but consist almost exclusively of phosphate and carbonate of lime. In the rabbit, rat, squirrel, and all Rodentia, it forms the cutting edge of their chisel-shaped incisor teeth.

The Cement (*c*) is a peculiar kind of nonvascular bone, and though small in quantity and comparatively unimportant in man, enters largely into the composition of the teeth in many of the lower animals. The statement advanced by Jean Jacques Rousseau, on the one hand, that man is a herbivorous animal, and by Helvetius on the other, to the effect that he is carnivorous, both seem to be refuted by the general characters of the teeth, so far as any evidence can be derived from such a source; for in this point of structure man occupies an intermediate position between the Carnivora and the Herbivora, and appears to be adapted for the consumption of both animal and vegetable substances, though doubtless life can be well preserved with a due selection and sufficient supply of either, as we shall subsequently see.

The lining of the mouth is a mucous membrane of considerable thickness, containing numerous glands, and covered with many tiers of tesselated epithelial cells, into the deep surface of which sensitive and vascular papillæ from the membrane itself project.

The movements of the lower upon the stationary upper jaw in man are effected by the muscles, exhibited in Figs. 2 and 3.

They comprise vertical, lateral, and backward and forward movements. The *depression* of the lower jaw is accomplished with considerable rapidity by the contraction of three or four small muscles—the digastric, stylo-genio, and mylo-hyoid—forming the floor of the mouth, the first-named being the principal agent in the Carnivora.

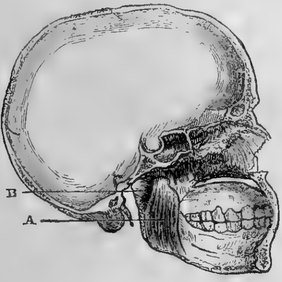

FIG. 3.—View of the internal muscles of mastication. A, *internal* pterygoid muscle; B, *external* pterygoid muscle.

From the position of the joint or pivot on which the lower jaw moves, the front teeth can be nearly twice as widely separated from one another as the back. The difference in the gape of the jaws varies in different people, and to a greater extent than might at first sight be supposed. In some measurements that I have made, I find that whilst the distance between the free borders of the front teeth does not, in some instances, exceed one inch, in others it amounts to upwards of two inches. The segment of a circle formed by the upper is usually somewhat larger than that of the lower jaw. Its *elevation*, which is a far more energetic movement, is performed by the temporal (A, Fig. 2), masseter (C, D, Fig. 2), and internal pterygoid muscles (A, Fig. 3). All these muscles are attached to the jaw between the fulcrum or condyle of the jaw, shown in Fig. 2, just in front of the external opening of the ear, and the weight to be moved or fore-part of the jaw. They therefore constitute levers of the third order; and hence, though acting promptly, are placed at a comparative disadvantage for exerting their fullest force. Still their power is immense even in man, who is again surpassed by many of the Carnivora. It is not easy to estimate it. I have endeavoured to do so, however, by ascertaining the pressure required to crush a Brazil-nut, which seems to be about the limit of the power possessed by young people with good teeth. At least very few can crush the stone of the peach. I find that a weight of about 84lb., but varying from 56lb. to 100lb. is requisite to break a Brazil-nut when placed on one of its flat sides, and this probably is not a very unfair representation of the average power of the three above-mentioned muscles. The lateral movements of the lower jaw are effected by the alternate contraction of the external pterygoids (B, Fig. 3), which are consequently seen in their highest state of development in the Ruminants. They are feeble in man. The forward and backward movements, also feeble, are due, the former to the external pterygoids, the latter to the deep portion of the masseter (C, Fig. 2), the posterior fibres of the temporal and the internal pterygoid.

Another muscle deserves to be noticed—the buccinator—which forms a considerable proportion of the thickness of the cheek, and which is an important agent in preventing the accumulation of food between the teeth and the cheek, the occurrence of which is so troublesome in some cases of paralysis. It is remarkable that all these muscles are supplied by one and the same nerve, the fifth; the last-named, however, receiving some additional motor filaments from the seventh or portiodura.

The movements of the tongue, which are under the influence of the hypoglossal nerve, are of very great importance also in aiding mastication, since its wonderful tactile sensibility enables us to feel for and thrust back between the teeth portions of food which have escaped their action. The centre for co-ordinating the various movements required for mastication appears to be situated in the medulla oblongata.

Having thus considered the mechanical process to which the food is subjected in the mouth, we shall proceed in another article to consider the chemical changes effected in it by the act of insalivation. H. POWER

NOTES

WE have more than once had to notice the liveliness recently exhibited by science at the Antipodes. This has now found expression in the issue of a monthly journal in Australia called "The Scientific Australian," a journal of industry and instruction, specially devoted to those engaged in scientific, artistic, and industrial pursuits, and to the promotion of technological education amongst the operative classes. The editor, Mr. J. S. Knight, Assoc. Inst. C.E., F.R.I.B.A., appears to have enlisted the services of the most eminent scientific men, not only in Victoria, but in the sister colonies of New South Wales, Queensland, South Australia, Western Australia, Tasmania, and New Zealand, and the articles, as a general rule, are to be signed. It is gratifying to find these signs of life in our colonies; we shall watch with interest the career of our contemporary, the first number of which was to be published at Melbourne on the 1st of the current month, and wish it every success.

AT the public sitting of the Paris Academy of Sciences, held on the 11th inst., the following prizes were awarded:—"The Astronomical Prize, Lalande foundation, to Mr. J. Watson, for the discovery of eight new asteroids in one year. The Mechanical Prize, Monthyon foundation, to M. Arson, for his experimental researches on the flow of gases in long conduits. Statistical Prize, Monthyon foundation, to M. Chenu, for his medico-chirurgical statistics of the Italian campaign of 1859-60. Prize established by the Marchioness Laplace, to M. F. A. Voisin. Trémont Prize to M. Le Roux, to aid and encourage him in the pursuit of researches on the index of refraction for certain vapours, and on the measurement of the heat developed by electric currents. Poncelet Prize to M. J. R. Mayer, of Heilbronn, for his memoirs on the mechanical theory of heat; Prize for Medicine and Surgery: a medal of the value of 3,000 francs, to MM. Legros and Onimus, for their works on the application of electricity to therapeutics; a medal of the value of 2,000 francs to M. Cyon, for a similar work. Prize for Experimental Physiology: to M. Famitzin for his researches on the influence of light on the nutrition of plants; a prize of 600 francs to MM. Tripier and Arloing for their discoveries respecting the cutaneous sensitive nerves. Prize for Medicine and Surgery, Monthyon foundation: a prize of 3,000 francs to M. Junod for his MS. work, entitled *Des médications hémospasique et aérothérapique;* two prizes of 2,000 francs to M. H. V. Luschka for his works on anatomy and to MM. Paulet and Sarazin for their treatise on topographic anatomy. Prize for the Unhealthy Arts: two prizes of 2,500 francs to M. Pimont for his *Calorifuge plastique* and to M. Charrière for his life-preservers. Bréant Prize: a prize of 5,000 francs to M. Fauvel for his works on the etiology and the prophylaxis of cholera. Cuvier Prize to Professor Ehrenberg, of Berlin. Bordin Prize, for a monograph of an invertebrate marine animal, divided between M. Marion, author of "Zoological and Anatomical Researches on the non-parasitic imarine Nematoïda," and M. A. Wagner, author of a monograph of the *Ancei* of the Gulf of Naples. Jecker Prize to M. Friedel, for his researches on the compounds of silicon corresponding to the compounds of organic origin. Barbier Prize, divided between M. Mirault on the surgical occlusion of the eyelids in the treatment of double ectropion, and M. B. Stilling, for the perfecting of the operation of ovariotomy. Godard Prize to M. Hyrtl, for his researches on the genito-urinal organs of fish. Desmazières Prize, divided between M. L. Rabenhorst for his European flora of fresh-water and marine algæ, and M. A. Hofmann, for his memoir on Bacteria. Thor Prize to M. Bonnet, for his work on the edible truffle. The Mathematical Prize of 3,000 francs, the Damoiseau Prize for the theory of the satellites of Jupiter, and the Medical and Surgical Prize for the application of electricity to therapeutics have not been awarded.

THE monument to Kepler, to which we alluded some weeks since, was inaugurated on the 24th June, with great *éclat*, at his native place, the little town of Weildiestadt, in Wurtemburg. The statue is of bronze, ten feet high, in a sitting posture. In his left hand, supported on a celestial globe, he holds a parchment on which is drawn an ellipse; in his right hand is an open compass; he is looking towards the heavens. The four corners of the pedestal are adorned with statues, five feet in height, representing M. Mastling, the Professor at Tübingen who taught Kepler mathematics, Copernicus, Tycho Brahé, and Jobst Byrg, the mechanician who assisted in the construction of his optical and astronomical instruments. In the centre of the pedestal is the single word, KEPLER; on each side are bas-reliefs, representing different circumstances in his life:—Kepler, at the age of seventeen, entering the lecture-room of Professor Mastling, at Tübingen, who holds the young pupil by the hand, and explains to him the Copernican system; the discussion between Tycho Brahé and Kepler on the system of the world, in the presence of the Emperor Rudolph and of Wallenstein; and Kepler and Byrg in their workshop at Prague, making their first use of the telescope for astronomical observations. The monument is the work of the sculptor, Kreling, director of the School of Fine Arts at Nüremberg; the statues and bas-reliefs were cast and chiselled in the workshops of MM. Lenz and Hérold in the same town; the pedestal of red sandstone, from a quarry in the neighbourhood of Weildiestadt, was constructed by the architect Egle, of Stuttgart.

AT the Working Men's International Exhibition now being held at the Agricultural Hall at Islington, one of the most interesting objects is a reflecting telescope, exhibited by Mr. T. W. Bush, a baker and grocer in one of the more humble streets of Nottingham. It has specula about thirteen inches in diameter, is equatorially mounted, and presents several novel features of construction that are claimed as improvements. Mr. Bush is a self-taught astronomer, mathematician, and mechanic. He has made, without assistance, the whole of the calculations necessary for the construction of the instrument, and has constructed the models for all its parts. With the exception of the prism and some of the more bulky parts, the whole of the telescope, the brass and iron work, the cutting of the sections, the graduation of the circles and verniers, the casting, grinding, and polishing of the metal speculum, the grinding and polishing of the glass speculum, and even the making of the tools and machinery required, have been the work of his own hands. The specula have been tested by Purkiss's process and proved correct, and the telescope has been found to divide satisfactorily such double stars as η Coronæ, ζ Boötis, and ζ Herculis. Its performance on the moon and on nebulæ is also very fine, and it has been used with a magnifying power of 1,400. Unfortunately, Mr. Bush lives in a low situation close to the River Lene, to a canal, and to smoke-yielding factories, and his observations have been hindered by the state of the atmosphere in his vicinity.

ANOTHER object of interest at the same Exhibition is a display of iron, obtained by a process invented by Sir Antonio Brady, from some of that dockyard refuse irreverently described as "Seely's pigs," and which has been the subject of discussion both in Parliament and by the Press. These pigs were of different qualities, but were all largely contaminated with phosphorus and sulphur, and were supposed to be of little or no value. The presence of phosphorus renders iron brittle when it is hot, the presence of sulphur renders it brittle when it is cold. The pigs containing both were worth in the market about 2*l*. 5*s*. per ton. By Sir Antonio's process the sulphur and the phosphorus can be extracted at a cost of about 35*s*. per ton, and the residual iron is superb. It bears any and every test. One of the pieces exhibited had been beaten cold to the thinness of writing paper at one end, drawn to a point at the other, and then twisted by hand eight turns in an inch at a single heating. Massive bars had been beaten cold until the surfaces on each side of the bend came into perfect contact, and a plate six inches wide and half-an-inch thick had been beaten till its edges were in contact, the flat surface remaining horizontal. In neither case were there any traces of a flaw either at the convexity of the curve, where the metal was stretched, or at the concavity, where it was compressed. Holes in a thick plate had been enlarged by driving cones into them, and, in a word, the iron had been knocked about in every possible way. At a very low estimate it is worth 14*l*. per ton, and as there is plenty of the raw material to be had, the profit of the invention seems likely to be great.

WE regret to have to announce the death, at the Villa Pisani, near Lucca, of A. H. Haliday, A.M., of Carnmoney, Co. Antrim, which event occurred on the morning of the 13th July. Mr. Haliday entered Trinity College, Dublin, in 1822, at the age of 15, and graduated five years afterwards as a gold medalist. Shortly after he was called to the bar; but he never practised. He was High Sheriff of Antrim in 1843. As an entomologist his name will always rank with those of his friends, Curtis, Sichel, Westwood, Dohrn, and Walker, while his quiet and retiring manners, and his great scholarship endeared him to a large circle of friends.

WE regret to have to announce the death of the distinguished Anglo-Saxon scholar, Mr. Benjamin Thorpe, which took place on Tuesday last, the 19th inst. Mr. Thorpe was in his eighty-eighth year.

A REPORT which has recently appeared in the papers about Dr. Livingstone, is referred to by Sir Roderick Murchison in a letter to the *Times*. The statement (communicated by Sir Thomas Maclear, late Astronomer Royal at the Cape of Good Hope) was that one Mr. Anderson, commanding a vessel bound from Zanzibar to the United States, had informed Sir Thomas, on or before the 14th of March, that Dr. Kirk, the consular agent at Zanzibar, had informed him that he had had a recent letter from Dr. Livingstone, who was quite well and about to proceed northwards. Sir Thomas Maclear had indeed (the president of the Geographical Society writes) "communicated the same to me; but I at once saw that the story was false, for I had in my possession a letter from Dr. Kirk, of two months' later date than the 14th of March, in which he could give me no information whatever respecting the great traveller. Since then I have again heard from Dr. Kirk at Zanzibar. I have for some time, and in concluding the geographical session, announced to all concerned that for at least eight months we did not expect to hear any definite news respecting Dr. Livingstone, inasmuch as the supplies and carriers to be sent to him and the answers to letters could not be obtained for a long period. I allude to those supplies which were obtained from Her Majesty's Government, and which only left England a few weeks ago."

WE cull this note from the *Pall Mall* and commend it to Mr. Lowe:—"To scientific English ears still tingling from Mr. Lowe's famous declaration as to Government aid to science, part of the proceedings in the Corps Législatif on Thursday last must have been very tantalising. Chapter 29 of the Budget contained an item of 800*l*. to assist Captain Gustave Lambert's expedition for the discovery of the North Pole. M. Stephen Liégeard moved that the grant should be 4,000*l*., and with the help of a few words from M. Picard his amendment was carried. To be sure it was the day before war was declared. M. Liégeard pressed a good many points into a brief speech. Since 1818 it appears there have been forty-two expeditions in search of this famous mathematical entity, all of which have failed. The three modes of search now urged are—that of Captain Sherard Osborn, by sledges over the frozen ocean (but, says M. Liégeard, what was thought to be a crust of ice is an open sea); the proposal of Augustus Petermann, of Gotha, to follow the route between Spitzbergen and Nova Zembla; and Captain Lambert's, to try the passage through Behring's Straits, which Cook would have done, "had he not fallen under the hatchet of the savages of the Sandwich Islands." It appears further that in the polar region, so fatal to explorers, "there are rich products to conquer—whale oil, fossil ivory, gold, copper, coal, and everything else that 800,000,000 of still unexplored polar hectares can conceal." Captain Lambert has held 200 meetings on this subject, and collected 16,000*l*., besides subscriptions from chambers of commerce, learned societies, the Emperor (2,000*l*.), and others. The exploring vessel, the *Boréal*, is ready; Captain Lambert, "an intelligent man, full of faith and courage, with a constitution of iron," will leave Paris on the 1st of February next, and in the month of August, 1871, so M. Liégeard says, he will—perhaps to the cry of Ohe! Lambert—"plant the French flag on the prolongation of the terrestrial axis." As for Captain Lambert, we do not wish to damp his courage or rust his constitution, but Voltaire wrote a curious prophetic sentence on the 30th of June, 1760, in a letter to Thiriot;—"Il vaut mieux attendre tout du temps en France que d'aller chercher l'ennui et le malheur sous le pôle."

AT a meeting of the Council of the Society of Arts, held on the 8th inst., M. de Lesseps received from the Prince of Wales the Albert gold medal for "services rendered to arts, manufactures, and commerce by the realisation of the Suez Canal."

THE testimonial to Professor Morris was presented on Thursday last by Sir R. I. Murchison in the rooms of the Geological Society, Somerset House.

L'ABBE MOIGNO makes an appeal in *Les Mondes* on behalf of the Niépce de Saint-Victor subscription, which at present hardly exceeds 400 francs; the widow is in great distress and wants the means for educating her two sons. As his inventions were of equal importance to French and English photographers, it seems fitting that England should bear her share in recognising his services. We shall be happy to receive subscriptions.

THE editorial chair of the *British Medical Journal* is about to become vacant. Candidates are to forward their application to the President of the Council, W. D. Husband, Esq., York, on or before the 30th inst.

IN reference to the recent appointment of Dr. A. R. Simpson to his late uncle's chair of midwifery in the University of Edinburgh, we have received a card with the following statements:—(1) That he had never given a course of lectures on midwifery, or on any other subject; (2) That he had never had a pupil (in the proper sense of the word); (3) That he had never held an hospital appointment; (4) That he had never sent in a single testimonial of his fitness for the chair to which he had been appointed; (5) That he had never written or published any paper that attracted considerable notice. The correctness of these facts being assumed, we can well understand the indignation of the faculty in London at the appointment, especially as one of the most eminent practitioners of this branch of surgery, Dr. Matthews Duncan, was a candidate. The time seems to have arrived when the appointment to Professorships in Scotch Universities should be placed in more competent hands than the Town Council. At the recent election the appointment rested with seven electors, four of them members of the Town Council, three men of distinguished literary and scientific position. The three latter voted for Dr. Duncan, the four baillies for Dr. Simpson, thus carrying the election by a majority of one.

M. CH. LE MAOUT calls attention in two recent numbers of *Cosmos*, to the popular belief that constant firing of guns has a tendency to bring down a heavy fall of rain, a belief which appears to be supported by the experience of the last Austro-Prussian war, the siege of Antwerp, and the battle of Solferino. M. Le Maout suggests that a series of experiments to test the soundness of the theory should be tried at the fortifications of Cherbourg, and at Brest, under opposite hygrometrical conditions, in the one case during a moist south, in the other during a dry east wind.

THE Acclimatisation Gardens in the Bois de Boulogne have just received from Java a fine female Orang, three years old, and larger than any that has hitherto been brought to Europe. It is described as extremely docile, and possessed of such a strong sense of propriety as to wash its bust, arms, and shoulders with soap and water whenever it feels to need it. It is allowed a walk every morning in the gardens, when it displays great activity in climbing to the top of the tallest trees. Its height when standing upright is about that of a child five years old.

THE Government of Nicaragua is trying to develop the waters of the Lake of Nejapa, which are reported to be efficacious in syphilitic affections of the system. The official report on the specimens sent to Paris states that the water is turbid, and contains a quantity of matter in suspension, having the smell of rotten eggs, due to sulphuretted hydrogen. The taste is alkaline. Such is the condition of the specimens in Paris, but in its natural situation the water is inoffensive in odour. The present analysis is therefore considered as capable of modification. The qualitative analysis gives us *bases*, magnesia, soda, potass, lime, iron, *acids*, sulphuric, hydrochloric, carbonic. The quantitative analysis states that 500 grains evaporated gave a residuum of 4·15 grains, which in treatment left, as the contents of each 500 grains of water

Bicarbonate of soda	1·90
,, potass	2·40
Sulphate of magnesia	0·55
Chloride of sodium	0·05
Sulphurets of calcium, iron, &c.	1·25

Although the analysis admits of correction with better specimens, it places the Nejapa water in the alkaline class with those of Vichy and Vals.

MR. G. H. HURLBUT, an American, has been appointed engineer to the Government of the United States of Columbia at a salary of 480*l*. per annum.

A LARGE public swimming-bath is proposed at Calcutta, and meets with support.

IN Bolivia there is great excitement in consequence of the discovery of rich silver mines in the Sierra del Limon Verde, fifteen miles from the small settlement of Calama, and seventy-five miles from the shore, in the maritime prefecture of Cobija. In a short time 150 mining licenses had been taken out at the prefecture, and there was a great rush from Cobija.

THE Queensland Acclimatisation Society have sent a parcel of seeds to the Peruvian Government. These have been placed in the Lima Botanic Garden, but are said tobe in bad condition. The Peruvian Government has communicated its thanks to H. B. M. Minister, and has directed a corresponding gift to be sent to the Queensland Society. The transaction has had a very good effect.

ANOTHER coal district has been discovered in India by Mr. W. T. Blanford, F.G.S., in the bed of the Hasdo river, just below the village of Korba, in the Bilaspore district. Mr. Blanford is of opinion that the seam is favourable for working, and that it surpasses the Chanda coal, and is in portions equal to that of Raneegunge.

IRON has been rediscovered in Gwalior in large quantities. It was formerly worked, but abandoned on account of the scarcity of fuel.

AT Chicholi in the Central Provinces of India, a vein of silver has been discovered yielding on assay 90z. 19dwts. 6grs. of silver to the ton of ore.

THE Observing Astronomical Society entered upon the second year of its existence on July 1st. The recent election of officers for the ensuing year has resulted tn the re-election of the former president, treasurer, and secretary and committee. The Rev. R. E. Hooppell, M.A., L.L.D., F.R.A.S., is the president; Mr. William F. Denning, the treasurer and secretary; and the following are the members of the committee: Messrs. S. P. Barkas, F.G.S.,; James Cook, A. W. Blacklock, M.B., H. Michell, Whitley, and Albert P. Holden. The society numbers forty-six members, and was formed for the purpose of aiding the spread of practical astronomy.

THE most recently published part of Martius's "Flora Brasiliensis" is an important one, comprising the ferns of Brazil (orders *Cyatheaceæ* and *Polypodiaceæ*) by Mr. J. G. Baker of the Kew Herbarium. Mr. Baker makes about 250 species; it is to be regretted that at the same time M. Fée had been working at Brazilian ferns from the very same materials in his *Cryptogamie vasculaire du Brésil*, which we have just received; and, following out the practice too much in vogue among Continental botanists, had made a distinct species of almost every slightly different form, thus enormously multiplying their number; his names will claim priority of publication over Mr. Baker's by a few months. The part is illustrated by fifty splendid plates, twenty of them nature-printed by Ettingshausen of Vienna, the remainder representing details of structure and fructification of every sub-genus, large plates of fifteen new and interesting species, and sections of trunks of the arborescent kinds. The *Hymenophyllaceæ*, *Gleicheniaceæ*, and other small orders by Sturm have been published some years; the *Isoetaceæ* and *Equisetaceæ*, by A. Braun, to be published very shortly, comprising only a small number of species, will complete the volume.

THE preparations for the New York Industrial Exhibition are making rapid progress, but it is not expected that it will be pened before the spring of 1872.

THE HARVEIAN ORATION

THE following extracts from Dr. Gull's Harveian oration, delivered at the Royal College of Physicians, on June 24th, form a fitting sequel to the researches of Dr. H. C. Bastian, which we reccently published, on the Spontaneous Generation of Living Things :—

"If it is ascertained beyond all doubt that, in respect of its materials, a living body contains no more than it has received; that, however strange and mysterious its organs and their functions, the warp and woof are of substances with which we are acquainted under simpler conditions, cannot the same be maintained of the forces it exhibits? . . . . It may be objected that there is lurking a kind of *petitio principii* in the supposed relations of simpler forces to their higher forms; that for the conversion of the former into the latter it is necessary to postulate material conditions of a certain kind, and that for the organic conversion we must begin with a living body or its germ; that the boast of the physiologist is like the boast of Archimedes. If he wanted a ποῦ στῶ, they require germs or ova and a living body. But it is clear that such an objection has no weight as in favour of a vital force which is not material, since it is abundantly proved that, whatever be the conditions required, they do not generate any power, but only vary the form of it. They who maintain the hypothesis of a separate vital force, independent of the ordinary forces of nature, and which has no essential relation to them, do, by the very terms of the hypothesis, assume that the phenomena in living things are out of the proper range of science, and they consign us to a perpetual mental inactivity and ignorance in that region of knowledge in which above all others man is interested. . . . . An hypothesis, like that of a separate vital principle, which demands so much, which stops inquiry at once, making progress impossible, by removing the steps by which it could ascend, should at least have the highest sanction of our intellect. . . . The dogma 'omne vivum ex ovo,' for the truth of which Harvey so justly contended against the fanciful notions of his age, cannot perhaps be now maintained in its integrity. Whether, to use an expression of that day, living things are ever produced automatically—that is, *de novo*—through putrefaction or otherwise, is, like the question of the limitation or universality of the germ power, still a matter upon which opinion is divided; and as it is my duty on this occasion to exhort you to investigate nature by way of experiment, I must ask you not readily to accept negative conclusions which impose limits where none may really exist. . . . . The time is passing in which the human mind can remain satisfied to rest under the fetters it has imposed upon itself, or to cherish its own phantasms, as if its very existence depended upon them. 'Man knows only what he has observed of the course of nature' is the notorious dictum of science, showing the limit and the mode of the acquirement of our knowledge: the limit as wide as nature itself; and the mode is but readiness to be taught. Notwithstanding, therefore, the adverse decision of schools and dogmas, science still occupies itself with the possibilities of occasional automatic generation. And that it should be so, let it not raise antagonism in the minds of those whose pursuits (inquiries) lie in another direction, since the infinity of nature may well include facts which at first seem to be antagonistic. . . . . We have lately been rather blamed for not gratefully accepting the germ theory of disease; but to this college the theory is not new, and, I think I may add, has not been proved to be true. It will be in the remembrance of many present that in the year 1849 a theory was put forth that epidemic cholera was due to fungi and their germs. Peculiar bodies, it was said, had been found in the rice-water evacuations, and also in the air and drinking waters of the infected localities. It was confidently asserted that we had substantial facts in support of the theory, and that it fulfilled the conditions required of being both true and sufficient. This college thought the subject of such moment that a sub-committee was formed from the Cholera Committee of that day for its investigation. The drinking water of infected places was examined, the air of rooms in which cholera patients were dying was condensed, that it might afford whatever floated in it for examination; dust was collected from cobwebs, window-frames, books, surfaces of exposed food, and every imaginable place, to try it for cholera germs. . . . The supposed germs, when really germs (for many shapes had been included in the supposed direful growth), were found to be spores of known harmless fungi and confervæ, of which, if even the startling number of thirty-seven and a half millions should be contained in about two drachms of water, as quoted by Tyndall, from Mr. Dancer's examination,* it is probable that the whole or repeated units of such millions might be harmlessly swallowed. But for the most part the supposed germs were not germs of any kind, but broken scraps of vegetable and animal tissues, spiral vessels from dried horse-dung, hairs, wings, and legs of insects, detrita of dress, and the like. The results were, in fact, entirely negative of any peculiar bodies to which the epidemic disease could be referred. One general result arrived at at that time, however, agrees with the observation of Tyndall in his recent investigation of dust by a beam of light—viz., that the floating particles in the air are chiefly of an organic nature. This we might have been prepared for, from the specific weight of dried organic material, enabling such dust to float, when the heavier inorganic substances would be deposited. That the infectious diseases spread by emanations from the sick, must have been long known, and that such emanations are of a solid nature, we may infer from the fact that they may be dried and conveyed from place to place; but in what state, whether as amorphous material or as germs, we know no more to-day than was known a thousand years past. No new fact bearing upon the propagation of contagious disease has been reached by the recent investigations on dust; nor can we infer the nature of summer catarrh because the nasal mucus under such circumstances and at no other time, was found peopled by vibriones, since decomposing mucus is always populous with this common race of infusoria. The phenomena of fermentation and putrefaction in dead and decomposing substances afford no explanation of the changes observed in a living body in a fever process. The purulent matter produced in small-pox, is not, as we know, in any way comparable to the yeast formed in fermenting fluids. On the contrary, the microscope demonstrates that the forms, as for instance in variolous pus, are not different from those contained in other purulent and innocuous exudations. Nor have we any reason to conclude that any forms which are observed are germs which convey the disease. It is to be regretted that a confusion in terms has been made. Instead of dust and disease it ought rather to have been dust and putrefaction, or dust and fermentation, since the relation of dust to disease has not been revealed anywhere in the inquiry. That the air conveys the material causes of the infectious diseases from the sick to the healthy, is a notorious fact, which had equal force before these inquiries were instituted, though, owing to the exigencies of social intercourse, a fact more neglected than in times of comparative ignorance. It is difficult to vindicate exactness in progress without seeming to be at the same time a hinderer of it. The onward and the regulating forces of a machine, though not incompatible, but necessary, require the nicest balance. This reflection suggests itself by the way the spread of infectious diseases has been handled. The theories it has given rise to have been so easily put forward as to thereby create distrust. But the spirit of science is no favourer of negations. 'Der Geist der stets verneint' finds no greater friend in medicine than in theology. Still it will be admitted that no progress can be made by the ready acceptance of every proposition, however distinguished the source from which it emanates. The parasitic origin and nature of epidemics *may* be true, but it has yet to be proved. As an hypothesis, it admits of proof or disproof, and so has further claim upon the industry of those who have put it forward as a suggestion. Without going to the length which this hypothesis demands, we must admit, however, that we know enough to uide us much further than we have yet gone in the practice of prevention."

* Proceedings of the Royal Institution of Great Britain, Jan. 21, 1870.

PROFESSOR TYNDALL'S LECTURES AT THE ROYAL INSTITUTION, ON ELECTRICAL PHENOMENA AND THEORIES

PROF. Tyndall completed a short course of seven lectures at the Royal Institution, on Thursday, June 9th, upon "Electrical Phenomena and Theories," which were made as interesting as all his lectures are, by the ingenuity and completeness of the experimental illustrations; in this particular case the apparatus of his distinguished predecessor, Faraday, being largely drawn up, in addition to considerable accessions of more recent date, many of them derived from the kind help of individuals who have made themselves high reputations in the various branches of Electrical Science. The scope of the Professor's demonstrations covered the entire range of Electrical and Magnetic Science, commencing with the phenomena of voltaic electricity, and passing through the various leading manifestations and peculiarities of electro-magnetism, magnetic force, frictional electricity, electro-chemistry, magneto-electricity, and, of course, electric telegraphy, and the relations of electric motive force to heat.

One remarkable peculiarity in these lectures of Professor Tyndall is, the effective way in which several of the more subtle effects of electrical change and power are made manifest to a large audience by the instrumentality of beams of electric light, manipulated in various ways. Thus, for instance, the elongation of a solid bar of iron, when it is thrown into the magnetic state, by being encircled in the folds of a voltaic current, conveyed by a helix, is shown by the starting of a spot of light, some six or eight inches upon a screen, when the molecular condition of magnetism is excited by the passage of the current. A beam of light falls upon a small mirror, carried at the extremities of the arm of a lever, so resting upon the end of the iron bar, that when the lever is lifted by the magnetic elongation of the bar, the beam of light is shot off from the mirror as a long weightless index. The change in the position of the molecules of iron by the action of magnetism is also proved by throwing the beam through a vertical cell of glass, containing magnetic oxide of iron suspended in water. When the cell is exposed to the influence of the poles of a strong electro-magnetic, the light passing through the cell and contained liquid to a screen beyond, brightens, in consequence of the metallic molecules turning themselves "end on" to the incidence of the beam. The lines of magnetic force assumed, when iron filings are sprinkled over the poles of a magnet, are portrayed by the intervention of a system of lenses, which depicts the image upon the screen. The formation of the "tree of lead" upon the negative electrode of a voltaic current, when a salt of lead is decomposed by the current, is shown in the same way; the arborescent crystals glowing and dissolving alternately on the opposite poles, immersed in the solution as the direction of the current is reversed. The very beautiful colours and patterns of Nohili's rings, formed when lead is thrown down by voltaic decomposition upon a polished plate of steel, are exhibited by a similar intervention of lenses, and the illumination from the electric beam. An artificial telegraph cable, whose resistance to the transmission of the electric current is made identical with 14,000 miles of an actual marine cable, is formed by introducing into the path of the current gaps, consisting of feebly conducting liquids and condensers, so distributed as to represent the respective distances by telegraphic route of Gibraltar, Malta, Suez, Aden, Bombay, Calcutta, Rangoon, Singapore, Java, and Australia. A mirror, belonging to each gap, lies in the path of the currents, carried by a galvanometer, constrained to deflect its needle from the position of both on the instant that the passage of the current is felt. Before the current is sent through the apparatus, ten dots of light, cast from the mirrors by the instrumentality of electric illumination, lie upon the screen, in a straight vertical range. When the current is passed through the apparatus, dot after dot starts aside upon the screen, as the current fills the condenser immediately before each mirror, and then flows beyond to deflect the galvanometer immediately in advance. The deflection of the successive galvanometers, and the corresponding traverse of the beam of light upon the screen, is seen, under this arrangement, to take place at successive steps or intervals, which exactly express the intervals of time which the electric current would require to reach the several stations named, in the actual progress of telegraphy. The starting aside of spot after spot upon the screen when the current is sent through the apparatus, and the subsequent return of spot after spot to the position of original test in inverse order, forms a very striking illustration of the fact that the resistance of an electric cable is in some degree dependent upon its length, and that time is consumed in overcoming this resistance. The most interesting and telling of all these beam-of-light illustrations, however, is certainly the one which is employed to indicate the excitement of diamagnetic force in a tube of copper, when it is suspended between the poles of an electro-magnetic. The tube is carried by a string of silk, and rotates rapidly under the influence of a twist given to the string. The string also carries above the tube a series of small mirrors, which reflect the light of an electric beam, so that a continuous elliptical band of illumination is formed on the screen whilst the twisting is continued. The instant the electro-magnet is made active by the transmission of the current through its helix, the copper tube acquires diamagnetic polarity by induction, and under the influence of this polarity the rotation is arrested, and the band of lights upon the screen is changed into a small stationary spot of illumination. When the electro-magnet is unmade by the arrest of the voltaic current, the spot of light again becomes an elliptical band, under the resumption of the twisting of the silk string with its mirrors and copper tube.

Of the numerous other very pleasing and telling illustrations exhibited in these lectures, space only permits allusion to be made to a very few which have been selected from the series, as being worthy of especial mention. The sound produced by the molecular vibration in iron when its mass is transiently magnetised by the voltaic current, is made audible by suspending an iron poker upon two sounding boards, and making it the core of a helix, conveying an electric current. An assistant is converted into an extemporised electrophorus, by flapping his black coat with fur while he stands upon a glass-legged stool. Small fish of gold leaf are made to float in the air current given off from the knob of a charged Leyden jar. A thick drinking glass is shattered by the expansion of the water contained in it, when sparks formed under the intensifying power of fifty condensers joined "in cascade," and primarily charged by a voltaic battery of one thousand cells, are passed through the liquid. To demonstrate the relation of resistance to heating power, a long line of wire is arranged in alternate links of platinum and silver, and when a voltaic current of due intensity is passed through the length, each stretch of the platinum wire is seen to glow with brilliant red heat, while the stretches of silver wire between remain still invisible. A beautiful series of Geissler's vacuum tubes were brought into successive operation, in which the auroral discharge was broken into stratified leaves, in which the glow was extinguished by the approximation of the poles of an electro-magnet, in which a feeble glow was converted into bright stratified light by the influence of a magnet; and beautiful beyond all the rest, the light from the enclosed negative terminal of the voltaic battery was arranged into the well-known lines of magnetic force, when subjected to the influence of the poles of a magnet.

It would be unnecessary in alluding to these very admirable lectures, to say one word of Prof. Tyndall's clearness and power as an expositor of the phenomena of Physical Science. These are now well known to the hundreds who are attracted to Albemarle Street on the frequently renewed occasions when the Professor performs this portion of his functions as a lecturer of the Royal Institution. It is, however, well worth while to draw attention to a device which the Professor adopts, with the happiest effect, to render his lectures as complete in their instruction as they can be made. He prints a series of well-digested "Notes" of the entire range of the subjects he passes over in each lecture, has them placed in the hands of each individual as he enters the lecture room, and then refers from time to time to the systematic outline, as occasion suggests the expediency of doing so. By this procedure the Professor is able to give full attention and time to each step of his illustrative demonstration, without being hampered with the need of telling everything that he has marked out beforehand—an extremely difficult thing to accomplish in a brief unextensible interval, where *viva voce* teaching has to be employed. Under this management any broken or omitted link in the full argument is readily recovered by glancing the eye over the range of printed notes after the conclusion of the lecture. This plan is well worthy of adoption, wherever popular lectures upon science are delivered to large audiences, with a view to instruction as well as amusement.

ZOOLOGY

Plateau on the Flight of Coleoptera

M. Felix Plateau has supplemented the recent labours of Marey and others upon the flight of insects by examining the movements of the wings of certain Coleoptera. Specimens of the common May-beetle and *Oryctes nasicornis* were selected for experiment. The apparatus used consisted of two pulleys, fastened one above the other, at a distance of two centimetres, on a vertical support; the upper pulley made twelve turns for each one made by the lower, and could be caused to rotate twenty-four times in a second. The insects were killed by ether vapour immediately before each experiment; and the wings could be fastened, by a simple contrivance, to the front prolongation of the axis of the upper pulley.

A wing, in its folded state, was fixed on the instrument in such a manner that its plane made, with the plane of rotation, an angle of 45°, as in the living animal. On turning the pulleys, it struck the air obliquely by its upper surface and front margin; but the small diameter of the apparently continuous revolving disc (as indicated by a graduated scale) proved that the wing was still folded, and that centrifugal force had not affected it. When rotation was produced in an opposite direction, so that the wing struck the air both by its posterior membranous margin and inferior surface, the increasing diameter of the disc gave proof of the expansion of the wing, which, indeed, continued to be much extended when motion was arrested. When the plane of a wing was perpendicular to the plane of rotation, and the revolution of the wheel was such that the wing struck the air by its dorsal or upper surface, no extension ensued; when it struck by its lower surface, only partial extension followed. Now the oblique, not the perpendicular plane is that chosen by nature, and is, as has been seen, much more favourable for flight.

On fixing an open wing on the axis so as to make an angle with the plane of rotation, and turning in one direction, the wing remained open; on reversing the direction (*i.e.* acting on the upper surface) it became partially closed.

SCIENTIFIC SERIALS

In the *Revue des Cours Scientifiques* for July 9, we have an important article on the Axioms of Geometry, by Prof. Helmholtz, which has, however, already appeared in an English form in the *Academy*, and the translation of an article by Mr. E. J. Reed, on *Navires blindés*; while M. Bernard concludes his course on Suffocation by the Fumes of Charcoal. In the number for July 16 there is an address by M. Dumas, delivered before the Academy of Sciences in honour of M. Pelouze, which occupies nearly the whole of the number, leaving room for only a short abstract of M. Bienaymés paper read before the Academy, on the military mortality in the Italian campaign of 1859-60.

Annales de Chimie et de Physique, May, 1870.—"Researches on the Gaseous Products of the Combustion of Coal," by M. A. Scheurer-Kestner. This important paper commences with an historical notice of experiments on this subject by Péclet, Ebelmen, Debette, Commines de Marsilly, Ebelmen and Sauvage, Foucou and Amiguis, and Cailleet, pointing out several causes of inaccuracy which are to be traced in their researches. The author then describes the process employed by him in collecting and analysing the gases from the flue of a steam boiler, Through the brickwork of the furnace a hole was bored, and in it was placed a platinum tube about 700 millimetres long and ten in diameter. To one end of this tube a copper pipe surrounded by a Liebig's condenser is soldered, the other end being closed with a plug. A narrow slit extends the whole length of the platinum tube, so that the air drawn through it is an average specimen of the gas in the flue. It is found also that the gas must be slowly aspirated through the slit in order to obtain a fair average of the gas passing through the flue during a considerable space of time. The author connected the apparatus with a water aspirator, by which he drew $\frac{1}{1000}$ of the total gas which passed up the chimney through the platinum tube; at the same time, from $\frac{1}{250}$ to $\frac{1}{500}$ of the aspirated gas was removed by a branch and collected in a bottle of three litres capacity, from which mercury was allowed to flow very slowly. Thus about $\frac{1}{500000}$ of the gas in the chimney was collected over mercury, and with this the analyses were performed. For the analytical processes we must refer the reader to the original paper, merely pointing out the conclusions at which the author has arrived. The gases of the chimneys were almost always found to contain carbonic oxide and hydrocarbons, even in the presence of oxygen arising from excess of atmospheric air. It was also found that the quantity of carbon lost in the form of smoke in the presence of sufficient air was about $\frac{1}{2}$ per cent., and that the loss of carbon as combustible gases does not exceed 2 or 3 per cent. when the excess of air amounts to 30 per cent. or more. The paper concludes with a section on the theory of the formation of smoke in the presence of an insufficient quantity of air, in which the author discusses the observations of Sainte-Claire Deville on dissociation, and of Berthelot on the action of heat on hydrocarbons, and points out their application to this subject.

To the number for June, 1870, M. P. P. Dehérain contributes an extremely interesting paper "On the Evaporation of Water and the Decomposition of Carbonic Acid by the Leaves of Vegetables." After mentioning the works of previous investigators, he describes the process adopted and the results obtained in his experiments. The leaves were surrounded by a very light flask with a wide and short neck, or by an ordinary test tube in the case of long and narrow leaves, like those of graminiferous plants. The difference between the weight of the globe or tube before and after the experiment gave the quantity of water which was condensed from the leaves. The author finds that the evaporation takes place quite readily, even when the atmosphere surrounding the leaves is saturated with moisture. Different species of plants evolve very different quantities of water under similar conditions, and the proportion of water seems to increase as the size of the leaf diminishes. Thus large leaves of colza evolved between 1 and 2 per cent. of their weight of water in an hour; smaller leaves 11 or 12 per cent., leaves of wheat between 70 and 90 per cent., and of rye between 90 and 100 per cent. In direct sunlight the water evaporated very much exceeds that emitted in diffuse light and in perfect darkness. Thus barley evolved 74·2 per cent. in direct sunlight, 18·0 per cent. in diffuse light, and only 2·3 per cent. in the dark. Numerous experiments are cited to show that this is not caused by heat alone, for when the tube was surrounded with cold water, or even with melting ice, the quantity of water collected was increased, doubtless owing to the more complete condensation of the water. Another series of experiments was made to determine if light of different colours had any influence on the amount of water excreted; and it was observed that yellow light, which also produces more rapid decomposition of carbonic anhydride under the influence of green leaves, is the most favourable to the evolution of water. It has recently been asserted by M. Prillieux that the variations observed when experimenting on the decomposition of carbonic anhydride by green leaves under the influence of light are influenced more by the intensity of the light than by its colour. M. Dehérain has performed numerous experiments with liquids of different colours, but of the same transparency, and shows that the yellow light is the most energetic, then follow red, blue, and finally green.—"On the Determination of Graphite in Cast Iron and Steel." By M. Boussingault. The author treats the iron with corrosive sublimate mixed with water, and heats the residue to volatilise the mercurous chloride. The black substance which is left consists of graphite, amorphous carbon, and silica. This is then heated in the air, the amorphous carbon burns off, and the loss of weight indicates the quantity of carbon in combination with the iron; the residue is next heated in oxygen, so as to cause the combustion of the graphite, which is likewise determined by loss. When the metal is dissolved in hydrochloric acid, the combined carbon is evolved in combination with hydrogen, and part of the silicon present passes into solution.

SOCIETIES AND ACADEMIES

Geological Society, June 22.—Mr. Joseph Prestwich, F.R.S., president, in the chair. Mr. Horace Pearce, 21, Hagley Road, Stourbridge, and Mr. Samuel Spruce, of Tamworth, were elected Fellows of the Society.

1. "Notes on the Lower portion of the Green-slates and Porphyries of the Lake District between Ulleswater and Keswick." By Dr. H. Alleyne Nicholson, F.R.S.E., F.G.S., lecturer on Natural History in the Medical School of Edinburgh. The author describes the characters presented by the lower part of that series of rocks, named by Professor Sedgwick the "Green-slates and Porphyries," which overlie the Skiddaw Slates in the Lake District. He notices the sections of this series in Borrowdale, on the east side of Derwentwater, between Keswick and the Vale of St. John, in the Vale of St. John, in Matterdale, in Eycott Hill, between Ulleswater and Haweswater, and in the neighbourhood of Shap. In the Borrowdale section the sequence of the rocks is given by the author as follows:—Resting on the Skiddaw slates there are (1) a felspathic trap; (2) a great series of ashes, breccias, and amygdaloids, often showing slaty cleavage and worked as slates, but with several intercalated bands of trap; and (3) a second trap. This appears to be a normal section, and is repeated, but diversified by the results of folding and faults in the other localities described by the author, except that in the Vale of St. John the true slaty series seems to be entirely wanting.

2. "Observations on some Vegetable Fossils from Victoria." By Dr. Ferdinand von Müller and Mr. R. Brough Smyth, F.G.S. Mr. Smyth stated that the fossils, of which specimens were forwarded by him, were obtained in one of the deep leads at Haddon, near Smythesdale. No leaves have been obtained from the bed, which consists of a greyish-black clay; the fruits and seed-vessels were obtained about 180 feet from the surface, and represent a flora not very dissimilar to that now characterising some parts of Queensland. The specimens sent include the fruits of a supposed new genus of Coniferæ, described by Dr. von Müller under the name of *Spondylostrobus*. It is most nearly allied to *Solenostrobus*, Bowerbank, but its five valves are not keeled. The columella forms the main body of the fruit; and the seeds are apparently solitary. The species was named *Spondylostrobus smythii*. The remaining specimens consisted of a solitary fruit of a genus of Verbenaceæ; an indehiscent compressed fruit, probably belonging to the Proteaceous genus *Helicia*; a nut nearly allied to the preceding; a large, spherical, unilocular, 3-seeded nut with a thick pericarp, perhaps from a Capparideous plant; a 5-valved capsule of an unknown genus; and fruit-valves of three other plants, probably belonging to the Sapindaceæ, and perhaps allied to *Cupania*. One of the last may belong to the Meliciaceous genus *Dysoxylon*. Dr. Müller considered that these remains indicate a former flora analogous to that of the existing forests-belt of Eastern Australia.

3. "Note on some Plesiosaurian Remains obtained by Mr. J. C. Mansel, F.G.S., in Kimmeridge Bay, Dorset." By Mr. J. W. Hulke, F.R.S., F.G.S. The remains described in this note represent two new species of *Plesiosaurus*. The dorsal vertebræ of the first species are distinguished by extremely short centra, with hollow articular faces. The antero-posterior diameter of 4 centra ranges between 1 and 1·3 inch, the transverse horizontal diameter between 4 and 4·6, and the vertical between 3·8 and 4 inches. For this Plesiosaur the author proposes the specific name of *P. brachistospondylus*. The other species, of which the greater part of the spinal column and portions of the breast and pelvic girdles and limbs are preserved, is a long slender-necked Plesiosaur exceeding 16 feet in length. Its limbs are much larger in proportion to the whole length than in the typical Liassic forms of this genus; but what particularly distinguishes it from these are the massiveness of the humerus and femur, the longer size of the wing-like expansion of the postaxial border, a well-developed trochanter, and especially three articular facets at the distal end of the femur, corresponding to which the second segment of the paddle, representing the leg, contains three coequal bones. The author noticed the impression of a third bone in this segment in the matrix, in which a paddle of *Pliosarurus portlandicus* is imbedded, and the ossicle on the postaxial border of the fibula in *Plesiosaurus rugosus*. He compared the paddle-bones of the Kimmeridge *Plesiosaurus* with those of *Ichthyosauri* and of the Liassic Plesiosaurs and of *Pliosaurus*, he drew attention to the very close resemblance of the humerus and femur to type specimens of the femora of *Pliosaurus brachydeirus* and *P. trochanterius* in the British Museum, and traced a similar resemblance between the elements of the cnemion and tarsus, and those of the Dorchester and Portland Pliosaurian paddles. For this creature, combining a long truly Plesiosaurian neck with Pliosaurian-like limbs, the author proposed the name of *Plesiosaurus manselii*.

4. "Notes on the Geology of the Lofoten Islands." By the Rev. T. G. Bonney, M.A., F.G.S., Tutor of St. John's College, Cambridge. The author described the general appearance of the Lofoten islands, which have commonly been described as composed of granite, but which he stated really consist of gneissic rocks. The scenery of some of the islands, on which he did not land, resembled that of the Cambrian and Cambro-Silurian districts of Wales and Cumberland; and the interior of Hassel showed dark rounded fells, resembling in outline some of the softer Welsh slates. At Stokmarknæs and at Melbo there is a granitoid rock of pinkish-grey colour, consisting of felspar and platy hornblende, with some mica and quartz. The Svolvaer Fjeld in Ost Vaagö shows a distinctly bedded structure in the cliffs near Svolvaer, the *débris* at the foot of which consist of a rock resembling syenite, and a quartzite containing a little hornblende and felspar. Bedding was also observed towards the Oxnæs Fjord. The islets near this coast consisted chiefly of a granitoid rock resembling a syenite, showing traces of bedding to the west of Svolvaer. Seams and veins of quartz, hornblende,

&c., occurred in some of the islets, and these were sometimes too regular to be explained by deposition in fissures. Near the Svolvaer post-office there was gneiss coarsely foliated, containing hornblende and mica, with pink orthoclase felspar. The author concluded, from his observations, that, with few exceptions, the so-called granites of the Lofoten islands are stratified, highly metamorphosed rocks, quartzites, and gneiss, generally with much felspar in the latter, and with more or less hornblende in both, and that they are inferior in position to the gneiss and schists of the mainland, and to the more slaty rocks of the southern and western parts of the same islands. He compares them with some gneiss from Dalbeg on the west coast of the island of Lewis.

5. "On *Dorypterus Hofmanni*, Germar, from the Marl-slate of Midderidge, Durham." By Mr. Albany Hancock, F.L.S., and Mr. Richard Howse. Communicated by Prof. Huxley, F.R.S., F.G.S. The material for this paper consisted of four specimens of *Dorypterus Hofmanni*, which have been discovered by Mr. Joseph Duff, in the marl-slate of Midderidge, and are believed to be the first examples of this fish which have been obtained in this country. The stratum from which they were procured is the same as that described by Prof. Sedgwick in his paper published in the Transactions of this Society (2nd series, vol. iii. pp. 76, 77). The specimens showed that the "ribbon-shaped" process mentioned by Germar is part of a peculiar exoskeleton, and that *Dorypterus* possessed ventral fins, which were situated in front of the pectorals, or "jugular." Hitherto no fishes with ventral fins other than "abdominal" in position have been known to occur earlier than the Cretaceous epoch. The tail is heterocercal, not homocercal, as Germar supposed. The dentition is not displayed in any of the specimens, and the teeth were probably small and inconspicuous; but the general structure of the fish shows it to be most nearly allied to the Pycnodonts.

6. "Observations on Ice-marks in Newfoundland." By Staff Commander J. H. Kerr, R.N., F.R.G.S. Communicated by the Royal Geographical Society. The author describes and tabulates the grooves and scratches observed by him on rock-surfaces in various parts of Newfoundland, especially Conception Bay, the neighbourhood of St. John's, and the north of Bonavista Bay. From the diversity of the direction of the markings and other considerations, he considers that they must have been produced by glaciers, and he believes that the main features of the country were much the same as at present before the glaciation took place. The author thinks that the land has not been submerged since it was freed from its coating of ice.

7. "On the Glacial Phenomena of Western Lancashire and Cheshire." By Mr. C. E. De Rance, F.G.S. The author described the general form of the ground and the preglacial condition and glacial deposits of the districts of Wirral and Western Lancashire, and draws from his observations the following general conclusions. That before and at the commencement of the glacial epoch the north-west of England was more elevated above the sea-level than at present, but afterwards gradually subsided, during which process marine denudation produced the plains of Wirral and Western Lancashire. Part of the latter has since been covered with glacial deposits 200 feet thick. The valleys running in the strike of the Triassic strata appear to have been formed by subaërial agencies. It is probable that when the glacial epoch commenced the hilly country was covered with immense glaciers, or with an ice-sheet, which, as the land sunk, reached the sea. The *High-level lower Boulder-clay* was probably produced by this land-ice. The land continued subsiding until it stood 100 feet lower than at present, submerging the lowlands of Lancashire and Cheshire to a depth of rather less than 25 fathoms, the coast-line being surrounded by an ice-foot, which received on its surface quantities of pebbles and boulders from the lake-district. These, on the breaking up of the ice-foot, were spread over the lowlands, forming the *Low-level Lower Boulder-clay*. The climate then improved, although subsidence still continued, and the sandy and gravelly deposits of the middle drift were produced; these deposits, at whatever elevation they occur, having been found in shallow water during the constant subsidence of the coast-line. The surface of the middle Drift shows traces of what seems to have been subaërial erosion, leading to the supposition that the land must have risen and suffered denudation before that depression during which the Upper Boulder-clay was deposited, at which period the climate again became extremely cold, and fresh glaciers were formed. Before the elevation of the Upper Boulder-clay the climate was greatly ameliorated.

8. "On the Preglacial Deposits of Western Lancashire and Cheshire." By Mr. C. E. De Rance, F.G.S. The author believed that after the deposition of the Esker Drift the country rose to from 200 to 300 feet higher than at present; but in the course of this elevation there was a pause, during which denudation took place, and the low plains, now covered with peat-moss, came into existence. From the consideration of the present depths of the channel between Great Britain and Ireland, the author inferred that an elevation of 200 feet would have caused the coast-line to run from the Mull of Galloway to St. David's Head; and Ireland would have been so connected with Wales as to render possible the migration of mammals, plants, and of man himself. Glaciers probably still persisted in the lake-district during the whole of this period of elevation. During a subsequent subsidence drainage became greatly obstructed, peat was formed, the sea encroached upon the land and worked its way eastward over the sea-bottom of postglacial times, a movement yet in progress. Here and there sand has begun to blow, forming dunes.

9. "Observations on Modern Glacial Action in Canada." By the Rev. W. Bleasdell, M.A., Rector of Trenton. Communicated by Principal Dawson, F.R.S., F.G.S. The author described some phenomena of ice-transport observed in Canada, especially those produced by the flood, anchor, or pack-ice produced in the rapids of the Canadian rivers. To this he attributed the entire disappearance of Crab Island in the River St. Lawrence, near Cornwall. This island occupied about an acre and a half within the memory of men now living; it has now entirely disappeared, and the water above it is gradually deepening. The island, according to the author, has been carried away piecemeal by the action of miniature icebergs, floated off by a rise in the water produced by a dam of anchor-ice below.

10. "On an altered Clay-bed and Sections in Tideswell Dale, Derbyshire." By the Rev. J. M. Mello, M.A., F.G.S. The author describes the sequence of the rocks seen in a quarry in Tideswell Dale as follows:—Beneath a thin layer of surface-soil is a bed of Toadstone, containing concretionary balls, and much decomposed above; beneath this is Toadstone in large blocks of indefinite shape, very hard, dark-green, and apparently doleritic, nine or ten feet thick, passing downwards into a coarse and much decomposed bed, partly amygdaloid, partly vesicular, about one foot thick. Beneath the Toadstone rocks, and without any sharp line of demarcation, is a thick bed of indurated red clay, three yards in thickness, presenting a regularly prismatic-columnar structure, resting on a thin bed of greenish-yellow clay, containing fragments of limestone, which covers beds of good Derbyshire marbles containing corals. The author suggests that the columnar clay-bed may perhaps be a local development of that which forms partings in the limestone near Litton Tunnel.

BRIGHTON

Brighton and Sussex Natural History Society, *Microscopical Section*. June 23.—Mr. Glaisyer, vice-president, in the chair. The subject for the evening was *Infusoria*, by Mr. Wonfor. Every one is aware that if any vegetable or animal substance is placed in water, in a few days the water will be found full of minute organisms, to which the name *Infusoria* or infusion animalcules has been given; many forms, though at first figured and described as distinct species, are now proved to be the early stages of other animals; others have been classed among another group of animals, and a larger number arranged among plants. The class *Infusoria* is much more limited than at one time supposed to be; and further, an increased knowledge might prove that many more were only the early stages of other and higher types of life. Mr. Wonfor then proceeded to point out the nature of their substance, their modes of development, increase, and propagation. So widely were they distributed that scarcely anywhere could water be found which did not contain some *Infusoria*. Many would live only in fresh water, others in salt or brackish water, while others were only to be met with in water containing decomposing vegetable or animal substances. Hence, water contaminated by sewage matter always showed certain types. While some were only to be found in particular infusions, others were common to several. Their appearance, under certain conditions, had led to theories on spontaneous generation, a much debated and debateable point; but as the atmosphere, according to Tyndall and others, appeared to be full of germs, their sudden appearance under favourable conditions was not surprising. The water in which cut flowers were kept was sure to yield some sorts; in fact, he had obtained an abundant supply of one kind from some water in which mignonette had been only three days. The water in bird fountains and in water bottles, if not looked after and frequently changed, would be sure to contain *Infusoria*. The rest of the evening was spent in examining the different forms of *Infusoria* brought for exhibition. Before separating it was announced that the subject for the next meeting in July, would be the "eggs of *Articulata*," *i.e.* of insects, &c.

PARIS

Academy of Sciences, July 4.—M. Serret presented a report upon a memoir by M. Bouquet, on the theory of ultra-elliptical integrals.—M. E. Catalan presented some remarks upon M. Darboux's note on the surface of the centres of curvature of an algebraic surface.—M. Janin read a reply to the observations of M. H. Sainte-Claire Deville, upon the variation of temperature produced by the mixing of two liquids, in which he discussed the theory proposed by M. Deville, and maintained the correctness of his own theory, according to which, he stated, the elevation of temperature of mixtures of liquids may be explained and calculated.—M. H. Sainte-Claire Deville made a few remarks upon M. Janin's paper, and also presented a third memoir on the action of water upon iron and of hydrogen upon oxide of iron, the results of which he sums up as follows :—The increase of tension of the hydrogen formed by the contact of iron and aqueous vapour is a continuous phenomenon when the tension of the aqueous vapour is caused to vary progressively without any change in the temperature of the iron ; the tension of the hydrogen corresponding to an invariable tension of the aqueous vapour decreases continuously when the temperature is gradually increased ; and the same laws are followed in the inverse phenomenon of the reduction of oxide of iron by hydrogen.—A note on a property of Volta's condenser, by M. P. Volpicelli, was read.—Some magnetic observations made at Makerstown, and at Trevandrum, near Cape Comorin, by M. Broun, were communicated.—An extract from a letter from M. Legrand to M. Jamin, on Deluc's thermometers, was read, in which the author stated that the difference between the temperature of the blood given by Deluc, and that now admitted, was due to the difference of atmospheric pressure at which the thermometers were graduated.—A note by M. Amagat, on the compressibility and dilatation of gases, was communicated by M. Balard.—M. Delaunay presented a note by MM. Wolf and Rayet on the light of Winnecke's Comet (Comet I. 1870) in which the authors describe their observations on the very feeble spectrum of that comet.—M. Delaunay also presented a note on the pyramids of Villejuif and Juvisy, the extremities of the geodetic base of Picard and Cassini.—M. Chapelas communicated a note on the spring of 1870, in which he noticed the phenomena of temperature, the direction of the winds, and the amount of rain observed at Paris during the months of April, May, and June of the present year.—M. Daudin communicated a memoir relating chiefly to the drought of the present year, which he ascribed to the prevalence of north-west and north-east winds, caused by some phenomena occurring in the Arctic regions.—M. Janin presented, in the name of M. Fonvielle, a notice of solar halos ; and M. C. Sainte-Claire Deville a note by M. Grad on the climate of Alsace and the Vosges.—M. A. W. Hofmann presented a note on the isomers of the cyanuricæthers in reply to M. S. Cloëz.—A paper on the phosphoplatinic compounds, by M. P. Schützenberger was read, in which the author announced that he had separated the radicals from the chlorine compounds described by him in his former paper.—M. A. Béchamp communicated a paper on the carbonic and alcoholic fermentation of acetate of soda and oxalate of ammonia, in which he described the growth of microscopic vegetation in solutions of those salts, and the production of alcohol thereby, from which he inferred that the synthesis of alcohol is effected by the vegetation, although the constituents of alcohol may not be present in solution. He went further, and stated that the same vegetation produced the same effect even in distilled water !—M. Elie de Beaumont presented a note on the rocks traversed in forming the tunnel between Modane and Bardonnèche in the Western Alps, a distance of 12,220 metres (or nearly 8 miles). The paper includes a long catalogue of the rocks observed, with their depths, which will prove of great value to the geologist.—M. Descloizeaux presented a note by M. C. Velain on the position of the *Terebratula janitor* limestones in the Basses-Alpes ; he referred them to the Neocomian stage, of which he regarded them as the lowest portion.—M. Duchartre communicated a note by M. E. Prillieux, containing an account of some experiments upon the withering of plants, also a note by M. Cave on the generatory zone of the appendages of plants.—M. Chantran presented some interesting observations on the natural history of the Cray-fish, in which he described the mode of copulation of those crustaceans, their oviposition and their changes of skin. The last-mentioned phenomenon takes place fifteen times in the course of the three years during which the animals grow to their adult state.—A note by M. J. B. Noulet contained a statement that in the neighbourhood of Toulouse the house martins all build their nests in accordance with what M. Pouchet calls the old fashion, that is to say, with a small round entrance notched in the upper margin of the nest. The swallows (*H. rustica*), on the contrary, according to the author, build nests resembling those described by M. Pouchet, and M. Noulet evidently considers that the latter naturalist has mistaken the nests of one bird for those of the other. Two physiological papers were communicated ; one on the vitality of the vaccine virus, by M. Melsens ; the other on an unequal production and difference of composition of the milk in the two breasts of the same woman.

PHILADELPHIA

Academy of Natural Sciences, February 1.—Dr. Ruschenberger, president, in the chair. The following paper was presented for publication : "Note on the relations of Synocladia, King (1849), to the proposed genus of Septopora, Prout (1858)." By F. B. Meek and A. H. Worthen.

March 1.—Dr. Ruschenberger, president, in the chair. The following paper was presented for publication : "Descriptions of new species and genera of fossils from the Palæozoic Rocks of the Western States." By F. B. Meek and A. H. Worthen. Prof. Leidy directed attention to a specimen received from the Smithsonian Institution for examination, which he said was the upper two-thirds of the right humerus of one of the extinct giant sloths, and was obtained in Central America by Capt. J. M. Dow. It agrees so nearly in form, proportions, and size, with the corresponding portion of the arm-bone of the *Mylodon robustus* of Buenos Ayres, as described and figured by Prof. Owen, as to render it probable it may belong to the same species. The specimen is unworn, black, not petrified, has no adherent rock matrix, and looks as if it had been obtained from alluvial mud. The interior of the shaft presents a long wide cavity, which might be viewed as the medullary cavity were it not that all the known extinct giant sloths have the limb bones solid. There would perhaps have been less hesitation in deciding as to the character of the cavity, were it not that comparatively recently a reverse condition was observed in a bone where it would not have been anticipated. A short time ago Mr. James Orton, of Rochester, N.Y., submitted for examination a collection of bones from the valley of Quito, Ecuador, S.A. The specimens were obtained at an altitude of 10,000 feet, and from Mr. Orton's account, were imbedded in a cliff of unstratified silt 400 feet in height. Among the bones, besides those of horses, lamas, &c., there was the femur apparently of a Mastodon, but solid or devoid of a medullary cavity. If the hollow interior be the natural condition of the *Mylodon*-like humerus under inspection, it would not belong to *Mylodon robustus*. Independently of the cavity indicated, the bone is sufficiently different in size and form to indicate a different species from the *Mylodon Harlani* of North America. The humerus from Oregon, described by Perkins (Am. Jour. Sci. 1841, xlii. 136), and referred to the latter by Prof. Owen, is not only much larger, but it is of greater breadth in relation with its antero-posterior diameter. The fragment of a humerus from Big-Bone-Lick, Kentucky, represented in fig. 3, plate xiv. of my "Memoir on the Extinct Sloth Tribe," is somewhat smaller than the corresponding part of the Oregon specimen, and is more compressed or wider in comparison with the antero-posterior diameter. Prof. Leidy further observed that there appeared to be a point of some significance in the anatomy of the mandible of *Dromatherium sylvestre* worthy of attention, though the appearance may turn out to be a deceptive one. Prof. Emmons had discovered three isolated rami of mandibles of this most ancient of American mammals in the triassic coal of North Carolina. Of the specimens, one is represented in fig. 66 of Emmon's American Geology, repeated in outline in fig. 650 of Dana's Geology. Another specimen Prof. Emmons presented to the Academy, and is contained in our museum. The point of interest to which reference is made is the apparent absence of a condyle. This process may have been lost, but in the two specimens seen by Prof. Leidy—that figured by Prof. Emmons, and that preserved in our museum—a separation of the process is not obvious.

March 8.—Dr. Carson, vice-president, in the chair. Prof. Leidy made the following remarks:—The reptilian remains from the cretaceous formation near Fort Wallace, Kansas, presented to the Academy by Dr. T. H. Turner, and described by Prof. Cope under the name of *Elasmosaurus platyurus*, belong to an Enaliosaurian, as originally suggested by Prof. Cope. The anatomical characters of the different regions of the vertebral column, those of the shoulder and pelvic girdles, and of the preserved portions of the skull and teeth, are decidedly Plesiosaurian.

March 15.—Dr. Ruschenberger, President, in the chair. The following paper was presented for publication:—"Cross Fertilisation and Law of Sex in Euphorbia." By Thomas Meehan. Mr. Charles Darwin's interesting observations on cross fertilisation have opened a new world for original discovery. The list of plants which seem to avoid self-fertilisation is already very large. I think *Euphorbia* may be added to the number. Certainly this is the case with *E. fulgens*, Karw. (*E. jacquinaflora*, Hook) which I have watched very closely in my greenhouse this winter. Several days before the stamens burst through the involucre, which closely invests them, the pistil with its ovarium on the long pedicel has protruded itself beyond, exposed its stigmatic surfaces, and received the pollen from the neighbouring flowers. The way in which the pollen scatters itself is curious. In most flowers a slight jar or a breath of wind will waft the pollen to the stigmas, but I have not been able to notice any to leave the flowers in this way; for as soon as the anther cells burst, the whole stamen falls from its filament-like pedicel and either drops at once on the pistils of other flowers or scatters its pollen grains by the force of the fall. This *Euphorbia* also furnishes another contribution to the theory of sex which I have advanced. The plan on which the male and female organs are formed is evidently a common one; and the only reason why some flower-heads have a pistil in the centre, and others are wholly staminate, is, that there is greater axial vigour when the female flower is formed. Whenever the common peduncle (below the scarlet involucre) is weak, a pistil never appears in that head of flowers. A few which seem strong neither have them, but the great majority of the strong peduncles are those which bear the female blossoms. Another interesting fact is that the number of male flowers is less in those heads which also bear a female, than in those which are wholly staminate. This seems to add to the point I made in my paper on *Ambrosia*, that after the flowers have been partially formed in embryo, and before the sex has been finally determined, the female flower, being primordially the stronger, has the power of absorbing the males or their partially formed elements into its system. It is certainly remarkable that in both these instances the number of male flowers should decrease in proportion to the existence or vigour of the central female one. The male and female flowers of *Euphorbia fulgens* are formed much alike. the female occupies the centre, and seems really but a prolongation of the main stem, on the top of which is an articulation from which the ovarium springs. The capsula readily falls from this articulation when mature. From the base of the female central peduncle spring weaker peduncles, colourless, appearing indeed almost like filaments, articulated at about the same height as the female, only above the point bearing a short filament and anther—the caduceous part before referred to. No one can fail to see the correspondence of plan in these different parts, and I think that nothing but the favourable position in the direct line of axial vigour made the central flower a female one. Cases occasionally occur in which a tolerably strong head of wholly male flowers will develop the central axis into a pedicel almost as long and vigorous as those which bear female flowers. But the flow of vital force—if I am correct in using this term —not being quite sufficient, the final goal of natural perfection in the female form was not reached. These cases do not occur often, but are well worth looking for, as they show so clearly the dividing line between the forces which govern the male or female sex.

March 22.—Dr. Carson, vice-president, in the chair. The following paper was presented for publication: "Descriptions of Fossils collected during the U.S. Geological Survey under the charge of Clarence King." By F. B. Meek.

April 5.—Dr. Carson, vice-president, in the chair. Prof. Leidy made the following remarks on "Discosaurus and its Allies." The body of the last vertebra in the series of caudals belonging to the Kansas saurian, described by Prof. Cope under the name of *Elasmosaurus*, has the length less than the depth or breadth, which latter is the greater diameter. It is moderately contracted towards the middle, the sides below the neural arch and the surface below the costal articulations being fore and aft concave, and bounded in front and behind by an acute margin from the articular ends. A ridge extends fore and aft between the chevron articulations, and the included surface is concave, and exhibits a single lateral venous foramen. The costal articular processes project from the middle of the side of the body, reaching nearer the fore than the back end of the latter. They are transversely oval, about three-fourths the length of the body, and the height about half. They form a deep concavity, with acute margins extending peripherally. The articular ends of the body are transversely oval and defined from the intermediate portion of the latter by an acute everted margin. A short distance within the position of the latter the surface is marked by a narrow groove, and within the circle of this groove the surface projects in such a manner as to appear like a distinct disc or epiphysial plate applied to and coössified with the body. The surface of the disc is convex at the periphery and moderately concave towards the centre. The articular surface beyond the groove defining the disc appears as an everted ledge, and the triangular articular facets for the chevrons appear as deflections of the ledge. The extension of the latter inferiorly is greater at the posterior extremity of the body than at the anterior extremity, thus producing a larger provision of surface in that position for the articulation of the chevron. The neural arch in the specimen has apparently been so much laterally compressed, that its original condition cannot be ascertained.

NATURAL HISTORY IN SCHOOLS

AMONG the many indications of the taste for natural science which is spreading throughout the country, there is none more striking than the rapid increase, during the last ten years, of local Field Clubs and Natural History Societies. Those who reside in our larger towns and can avail themselves of every facility for prosecuting their favourite branch of study, are apt to under-estimate the value of these bodies, and to look upon them as merely accessories to the bringing together, under the name of science, of men of congenial tastes, rather than as performing any definite or actual work; but this is an error which can only arise in the minds of those who have had no opportunity of seeing the working of such societies, and who have not therefore felt the advantages by which membership is attended in a remote country district. No doubt there are, here and there, Field Clubs which fall short of the perfection they ought to attain; but that these are the exception, and not the rule, no one who has investigated the matter can reasonably doubt.

It is not, however, to such societies that we would now direct attention, so much as to the rise and progress in our public and private schools, of bodies whose aim and object is the same; a progress which is the more gratifying when we remember that it mainly originates with the boys themselves. As to the value of such societies there cannot be two opinions. We would not for a moment depreciate cricket and other manly sports; but we would supply for the mind a rational substitute for such manias as that of postage-stamp collecting, which a short time ago reigned in our schools.

It may not be known to many who are aware of the existence of such societies in our larger schools, that their origin dates back nearly forty years. It is to the York School, under the superintendence of the Society of Friends, that we must look for the first step in this direction. In 1834—three years after the formation of the Berwickshire Field Club, then the only one of its kind in the kingdom—a Natural History Society was formed in the York School, which is in operation at the present time. Quiet and unpretending, few even of those who take an interest in such societies are aware of its existence, or have seen the modest report which it issues year by year. Had Mr. Carlyle, in his schoolboy days, shared such advantages, we should not have him now lamenting that no one ever taught him the constellations, or "made him at home in the starry heavens!" Looking through the names of members, formerly pupils at the school, we note among them men now known to science; and we shall scarcely be wrong in supposing that science is in a great measure indebted to the York School for the work which they have done, and are still doing.

Turning now to our public schools, the first which claims our notice is Marlborough College. In 1863, the Rev. T. A. Preston, one of the masters, assisted by some of the pupils, published a Flora of Marlborough, "with a hope that, by placing before the members of the college a proof of the botanical riches of our neighbourhood," he might induce some of them to take an interest in the study of botany, and perhaps indirectly through this, of some other branch of Natural History. How far this hope was realised may be gathered from the fact that, in a few months "a spontaneous movement arose among certain members of the school towards the pursuit of Natural History with some degree of system and organisation." The *Marlborough College Natural History Society* was speedily formed, Mr. Preston being elected president, and to him we are indebted for a complete set of the reports issued by the Society, containing the rules, the papers read, and the calendars—ornithological, botanical, and entomological, for the various years. As it is mainly upon the model set by this Society that other similar ones have been formed, a few details may be interesting. The rules strike us as being particularly good, and might be adopted with advantage by Field Clubs generally, although some of the best of them, such as that providing for the exclusion of members who do not evince sufficient energy in the working of the club, could only be satisfactorily carried out in school societies. Glancing through the papers, their general excellence, as well as the variety of subjects, is worthy of note. Not that all are of equal value; this indeed it would not be reasonable to expect; but taking them as a whole, they would be creditable to members of "grown-up" societies. Due prominence is given to those bearing upon matters of local interest, and new discoveries in science are brought before the members. The various calendars are most carefully compiled, and are so printed as to indicate each year's additions to the flora and fauna of the district; the number of members cited as contributing gives us a good idea of the actual work done by the Society. Besides these transactions, a museum has been established, and judging from the numerous contributions acknowledged in the reports, it is assuming very satisfactory proportions. The formation of a museum is a work peculiarly suitable to a school; a common centre, so to speak, is provided, upon which to work; the objects collected are sure to be carefully preserved, and the collection is in a position where it may be of real service to those interested in it. A library has also been formed, and we may suggest to any of our readers who may happen to have on their shelves duplicate copies of any scientific work, that they cannot do better than forward them for the use of such a body.

The *Harrow School Scientific Society* was founded in 1865, but here, as at Marlborough, considerable interest had been manifested in Natural Science for some time previously, as was evidenced by the publication, in 1864, of a Harrow Flora, with chapters on the birds and insects, all by Harrovians. The printed reports give selections from the papers read, which, if not equal to those of the Marlborough Society, are still creditable; we have, however, no calendars, and the additions to the fauna and flora are comparatively few.

The *Rugby School Natural History Society* dates from March 1867, and has issued two reports. The most noticeable feature in the published papers is the prominence given to subjects bearing upon the Darwinian theory of the origin of species, and some extremely thoughtful essays on this, as well as on the more recent facts which support the theory, are printed. Some papers on the "Protective Resemblances," noticeable among British, as well as foreign insects, seem to us particularly suggestive; the natural history of the district receives a due share of attention, and in the two reports before us we have lists of the birds, Lepidoptera, and flowering plants, with dates of appearance, record of new species, &c., besides a copious list of local Lias fossils. A museum and library are in course of formation.

The *Wellington College Natural History Society* held its first meeting on May 13, 1868, and its rules are based upon those of the Rugby Society. One report only has as yet been published, in which we find selections from the papers, including one by Professor Kingsley. Botanical and ornithological lists are given, but the comparatively recent formation of the Society renders any detailed criticism unnecessary.

Last comes the *Winchester College Natural History Society*, established in March last, a notice of which has already appeared in NATURE. Of course little has been done, and nothing published at present; but we learn from the secretary that the plan of working by sections has been adopted, and that the meetings are well attended. To this and to all similar bodies we heartily wish success.

We are sorry to see that Eton is "conspicuous by its absence" from our list. The publication, two years since, of "The Birds of Berkshire and Buckinghamshire," by Mr. Clark-Kennedy, "an Eton boy," induced us to hope that a school which in position is second to none, would not be left behind in the onward march; but as far as we can ascertain, nothing in the way of a society has been established at present. We shall be glad to learn that we are mistaken in this matter, and trust that, even should no such body at present exist, it may not be long before we hear of its formation.

THE RELATIVE VALUE OF CLASSICAL AND SCIENTIFIC TRAINING

Wodurch die humanistischen Gymnasien für die Universität vorbereiten? Rede an die Studirenden der Ludwig-Maximilian's Universität zu München gehalten am 4 Dezember, 1869, von Dr. Med. Max v. Pettenkofer, Professor der Hygiène, z. z. Rector. (München, 1869.)*

THE German-reading public can possess itself at a very trifling cost of a very weighty opinion as to the relative value of classical and of scientific training, by the purchase of an address delivered last December in Munich by Professor Max v. Pettenkofer, in his capacity of Rector or Chancellor of the University for the time being. There is in existence an English document (we fear we cannot speak of it as a *publication*) in the shape of a report, laid before the authorities of Owens College, Manchester, which has appended to it a name nearly, or quite, as familiar to the student and readers of NATURE as Pettenkofer's—viz., that of Professor Roscoe, and in which the same process of "ponderation" is applied to the classical "Gymnasia" and the modern "Real-Gymnasien" severally. V. Pettenkofer, who is not referred to in that report, shall here speak for himself, and we may say at once, that after stating more or less fully the objections which are ordinarily urged against the classical system, he declares himself an adherent of the party which stands *super antiquas vias*. The two delegates of Owens College appear to incline in the same direction somewhat, but are more eclectic and more careful in balancing their utterances as to the possibility of combining the two systems than either v. Pettenkofer, whom we shall forthwith cite on the one, or than Helmholtz, whom they cite on the other side.

The argument from authority has a legitimate place in questions concerning such matters as the genesis of culture and as the existence of capacity and capabilities; for in such questions neither the facts themselves nor the mode of their origination can be always looked upon as beyond the region of probability. But as we are writing in a scientific periodical, we will begin at least with something which admits of being quantitatively estimated; and we will do this by giving the time-tables of the classical (*Humanistischen*) and of the modern (*Real-Gymnasien*) schools in Bavaria, as we find them in v. Pettenkofer's address (pp. 5 and 18).

In classical schools, out of 99 hours per week:—

8 hours per week are given to			German.
26	,,	,,	Latin.
22	,,	,,	Greek.
8	,,	,,	French.

(*i.e.*, 64 hours, or 65 per cent., are given to languages, three-fourths being Latin and Greek, and one-fourth German and French.)

17 hours per week are given to			Mathematics.
10	,,	,,	History.
8	,,	,,	Religious Instruction.

In "Real-Gymnasien," out of 112 hours per week:—

9 hours per week are given to			German.
14	,,	,,	Latin.
13	,,	,,	French.
4	,,	,,	English.

(*i.e.*, 40 hours, or 33 per cent., are given to languages, of which time only one-third is given to one ancient language, one-third to French, the other two-thirds to German)

27 hours per week are given to Mathematics.

(*i.e.*, algebra, elementary geometry, trigonometry, descriptive and analytical geometry and higher analysis, taking 22 per cent. of the whole number)

4 hours per week are given to			History.
19	,,	,,	Natural Science and Geography.
24	,,	,,	Drawing and Modelling.
8	,,	,,	Religious Instruction.

The "Real-Gymnasien" are thus seen to exact 25 per cent. more hours than the classical schools; and it is by this increase on the one hand, coupled with a curtailment of the quota assigned to languages on the other, that time is found for mathematics and for natural science, with the drawing and modelling so indispensable to it. V. Pettenkofer deprecates the making of any material increase in the number of hours to be spent in the gymnasien, on the undeniable ground that the day is no longer, and man no stronger now than were the days and the men of 2,000 years ago; and space for such additamenta as must be made to the curriculum must be found by

* "In what way do classical schools give students a preparation for the University?" An address delivered to the students of the Ludwig-Maximilian University in Munich, on the 4th of December, 1869, by Max. v. Pettenkofer, M.D., Professor of Hygiène, and at the time Rector of the University. (Munich, 1869.)

bettering the methods and means for communicating instruction, and effecting thus an economy of time.*

The Bavarian chemist and hygienist does not himself suggest any ways and means whereby this economy may be effected, and presumptuous though it be, we will attempt to supplement this deficiency by saying that such an economy might be effected in England and English schools by applying one or other or all three of the following lines of treatment to the classical curriculum, even without cutting its Greek adrift. Latin and Greek, to put the boldest suggestion first, might be studied in certain, and those not a few, cases, as literatures and not as philologies; or, as a second alternative, when some training in philology is to be retained at whatever cost, such training might be made more intelligible and so less distasteful and wasteful of time, by making the study of it comparative, as recommended by Professor Max Müller in his evidence before the Commission just referred to; or thirdly, synthetical scholarship, in the way of verse-making, should be considered as a luxury and refinement to be reserved for the delectation and cultivation of those few who, in any age, show any aptitude for it, and synthetical scholarship in the way even of writing Latin prose might, due precautions having been taken, be dispensed with in the cases of youths who, whilst wholly incapable in that, had shown some capacity in some other line. Our "due precautions" should consist in the multiplying the practice of synthetical scholarship in the way of translation from Latin into English. We know the horror which these suggestions will excite in the breasts of schoolmasters of the type represented by the gentleman who told the Commissioners already referred to, that if he were set to teach History in set lessons, he "should not know how to do it." But we believe that by the adoption of any one of the three lines of action just glanced at, space and time might be found for the introduction of the natural sciences into the curriculum of any public school, and that at once without injury to the dignity of either the one or the other of the two sets of studies, and without injury to the physical or mental health of the learners.

But it is time, perhaps, that we should let v. Pettenkofer speak for himself; and this he does (at p. 12, *l. c.*) to the following effect:—"I am convinced that philology and mathematics furnish precisely the material for teaching and intellectual discipline which is essential for our gymnasia, and I look upon the material furnished by other sciences as mere accessories. I know that in putting forward this view, which I do not do now for the first time, I put myself into opposition with the tide of opinion which is prevalent just at present, and which anticipates great advantages from the introduction of additional subjects of instruction, and especially from the introduction of instruction in natural science into 'Latin schools (Lateinschulen) and gymnasia.'" Further on (p. 16) he proceeds as follows:—"The results of actual experience appear to me to favour my views. In other parts of Germany, experiments have now, for a long while, been made with gymnasia and similar institutions, in which much natural science is taught. But I cannot as yet discover that any remarkable number of persons who have subsequently distinguished themselves in natural science have come from these schools. In this matter reliable statistics of the pupils leaving (*der Abiturienten*) a Berlin gymnasium, the so-called 'Old Cologne Gymnasium,' in which natural science has for a long while formed part of the curriculum, would be very instructive. Distinguished men come, from time to time, from this gymnasium, but certainly not in greater numbers than from any other classical (*Humanistischen*) gymnasium where no natural science at all is taught. It would long ago have been a notorious fact if a disproportionate number of the younger professors of natural science in the Prussian Universities could have been shown to have been formerly students in the Cologne Gymnasium."
